UNIQUE

Full-cycle endometrial support, with no late-cycle progestin increase.

The unique TRI-NORINYL phasing achieves BTB control equivalent to a 1/35 formulation, but with 29% less progestin per cycle. This is, in fact, the greatest progestin reduction of any norethindrone-based multiphasic. TRI-NORINYL lowers progestin where requirements for endometrial support are reduced—with no greater reported BTB than a 1/35 formulation.*

SUPPLIED IN THE EXCLUSIVE SYNTEX WALLETTE™ PILL DISPENSER

Preferred by patients 3 to 1 over other available packages for convenience, discreetness and compliance.**

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

*1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. Data available from Syntex Laboratories, Inc.

**Based on a nationwide, independently conducted survey of prospective oral contraceptive patients. Data available from Syntex Laboratories, Inc.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to non-smoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34–5/100,000; ages 35-44–33/100,000; ages 45-49–140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34–1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over–1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS–RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A–Use associated with very high risk.
B–Use associated with high risk.
C–Use associated with moderate risk.
D–Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones–estrogenic and progestational agents–during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests *Chlamydia trachomatis* infection, the leading cause of nongonococcal PI.D., is enhanced by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

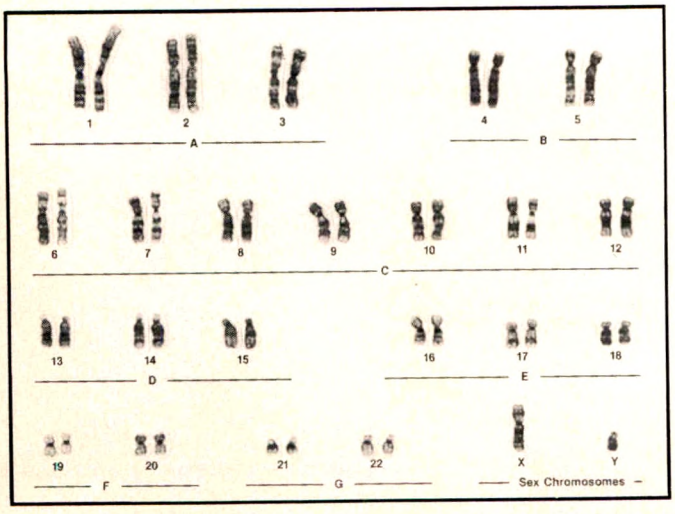
When you need genetic testing results . . .

S SERVICE

Vivigen operates a full service genetic testing laboratory, offering chromosome analysis on amniocentesis, blood, and bone marrow specimens, as well as AFP and Tay-Sachs carrier screening tests. Full service means prepaid overnight shipping of specimens in Vivigen packing kits, fast turn-around time, thorough and accurate analysis, and individual consultation with physicians at any time.

T TECHNOLOGY

The medical staff at Vivigen is well qualified and experienced in the field of genetics. Kathleen E. Richkind, Ph.D., Laboratory Director, Stirling M. Puck, M.D., Director of Medical Genetics, and Kirk A. Aleck, M.D., Director of Biochemical Genetics, are all Board certified by the American Board of Medical Genetics. They are supported by a highly trained staff, who are licensed in their respective areas of technical competence.



A ACCURACY

Physicians at major university medical centers, HMOs, and in private practice all choose Vivigen for its reliability and accurate results. The laboratory is approved by the College of American Pathologists, licensed by CLIA and the state of New York, and voluntarily participates in quality control programs run by CAP, New York, the Foundation for Blood Research, and the International Tay-Sachs Testing Quality Control Panel.

T TURN-AROUND

Amniocentesis and the long wait for results (two to four weeks for most laboratories) cause tremendous anxiety among patients and their families. Vivigen's turn-around time averages only seven days, shortening this waiting period dramatically and providing an extra margin of safety should further testing or action be required. Physicians in nineteen states across the country rely on Vivigen for genetic testing.

TURN-AROUND: 7 Days for Amniocentesis Specimens

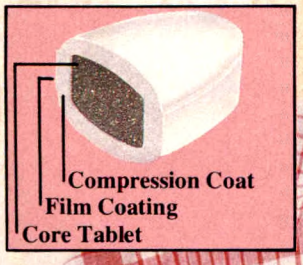
Natalins® Rx

Multivitamin and Multimineral Supplement with 1 mg Folic Acid

The Only Prenatal Vitamin with No Artificial Color or Flavor from Synthetic Sources

The Recipe for Prenatal Good Health



Good things are made from the finest ingredients. And the ingredients for maintaining good prenatal health make NATALINS Rx a standout . . . inside and out.

NATALINS Rx is the first and only prescription vitamin and mineral supplement with "natural" color and flavor. It contains all the mandatory and optional vitamins and minerals, plus copper and zinc, both important in the metabolic process.

Unique NATALINS Rx Construction Aids Compliance and Maintenance of Good Health

An elliptical tablet shape and a cellulosic film coating that becomes slippery when wet allows for easier, more comfortable swallowing—aiding patient compliance. Beneath the special coating, a central "core tablet" stores iron for delayed release, reducing the risk of stomach upset.

NATALINS Rx . . . the "Natural" Choice for Prenatal Good Health.

NATALINS® Rx

Ingredients	Natalins Rx	
VITAMINS	**Units**	**% RDA**
Vitamin A, IU	8000	100

Magnesium, mg	100	22
Copper, mg	2	100
Zinc, mg	15	100
Artificial color	none	
Artificial flavor	none	

Natalins Rx is a multivitamin, multimineral supplement for pregnant or lactating women. Daily dose: 1 tablet or as prescribed.
Contraindications: Natalins Rx should not be prescribed in patients with hemochromatosis or patients with Wilson's disease.
Caution: Pernicious anemia should be excluded before using this product. In patients with kidney stones, the calcium content of Natalins Rx tablets should be considered before prescribing.
Supplied: Bottles of 100 and 1,000.

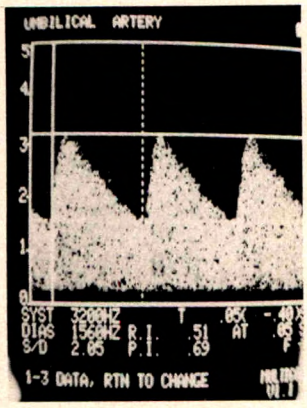
MULTIGON INDUSTRIES, INC.

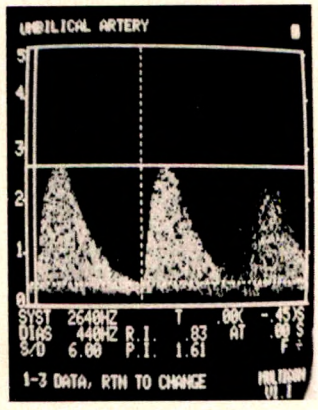
500A™ UMBILICAL-UTERINE ARTERY DOPPLER SPECTRUM ANALYZER

LETS YOU EVALUATE

UTEROPLACENTAL PERFUSION BY SPECTRUM ANALYSIS OF UMBILICAL AND MATERNAL UTERINE ARTERY DOPPLER WAVEFORMS



CLINICAL RESULTS[1-8] SHOW THAT YOU CAN:



- DETECT *IUGR* FROM 20 WEEKS IN SINGLETON PREGNANCIES AND 30 WEEKS IN TWIN PREGNANCIES
- USE UTERINE ARTERY WAVEFORMS IN THE MANAGEMENT OF MATERNAL PREECLAMPSIA
- USE UMBILICAL ARTERY VELOCITY WAVEFORMS IN THE MANAGEMENT OF DIABETIC PREGNANCIES

Umbilical and uterine artery waveforms are easily obtained from early pregnancy on. Low power continuous wave Doppler spectrum analysis is used in a simple test to measure the peripheral resistance in the placental circulation. This resistance is measured by taking the ratio of the systolic to diastolic (S/D) velocity. The S/D ratio is compared to established normal values to determine the presence of abnormal resistance.

The Model 500A™ automatically computes the systolic to diastolic ratio as well as resistance and pulsatility indices.

Normal Umbilical Waveform
S/D = 2.05

Abnormal Umbilical Waveform
S/D = 6.00

There's never been a better time for her

and PREMARIN®

Proven benefits beyond relief of vasomotor symptoms

No other estrogen proven effective for osteoporosis

Only conjugated estrogens tablets have established efficacy in both osteoporosis[1] and vasomotor symptoms* at 0.625 mg/day. No other estrogen, oral or transdermal, has established clinical evidence or minimum effective dose in both indications.

No estrogen proven safer

PREMARIN is the most extensively tested estrogen, with an unsurpassed record of long-term safety.
And clinical evidence shows a significantly reduced risk of endometrial hyperplasia when cycled with a progestin.[2]

PREMARIN®
(conjugated estrogens tablets)

Most trusted for more reasons

*PREMARIN is indicated for moderate-to-severe vasomotor symptoms.

Please see following page for brief summary of prescribing information.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equi-estrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: PREMARIN (conjugated estrogens tablets, USP): Moderate-to-severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. (See PRECAUTIONS.) The choice of progestin and dosage may be important; product labeling should be reviewed to minimize possible adverse effects.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not yet complete. If concomitant progestin therapy is used, potential risks may include adverse effects on carbohydrate and lipid metabolism.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. However, in a recent, large case-controlled study of postmenopausal women there was no increase in risk of breast cancer with use of conjugated estrogens.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration. Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off). Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

DEFINING THE DIRECTION OF OC EVOLUTION

WITH THE ADVANCED DESIGN OF

TRI-LEVLEN™

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

No other OC regimen phases *both* hormones

▼

Provides the *lowest* monthly dose of both estrogen and progestogen

▼

Little or no effect on lipid metabolism[1-5]*

▼

Low overall incidence of breakthrough bleeding[6]

*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These data represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

TRI·LEVLEN™ 28
TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxy-gon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses. The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

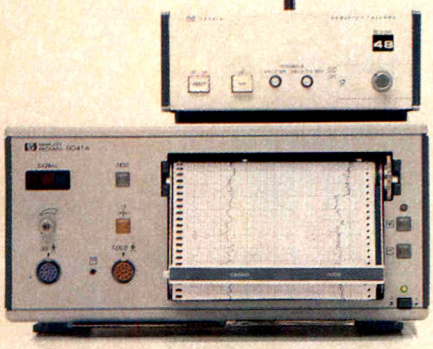
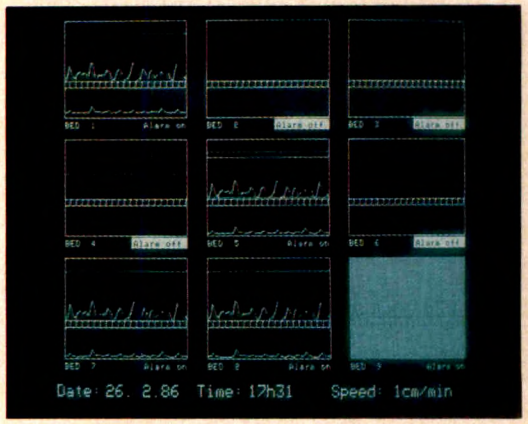
Hewlett-Packar
OB environmen



A new environment has just arrived in OB. It's one with greater comfort for patients. Greater flexibility for the OB staff. And a level of monitoring dependability that provides peace of mind for everyone. It's the result of new, innovative equipment from HP. It gives both the OB staff and patients a whole new level of flexibility and freedom.

Non-invasive fetal ultrasound telemetry: Allowing mothers-to-be to move freely. HP's new external fetal ultrasound telemetry gives expectant mothers the physiological benefits of ambulation while providing continuous monitoring of fetal heart rate and uterine activity. And it does it with a minimum of inconvenience. The patient's only contact with the unit are two transducers on the abdomen and a small, pocket-sized unit that transmits data to a receiver linked to a bedside fetal monitor.

d brings a new t into the world.

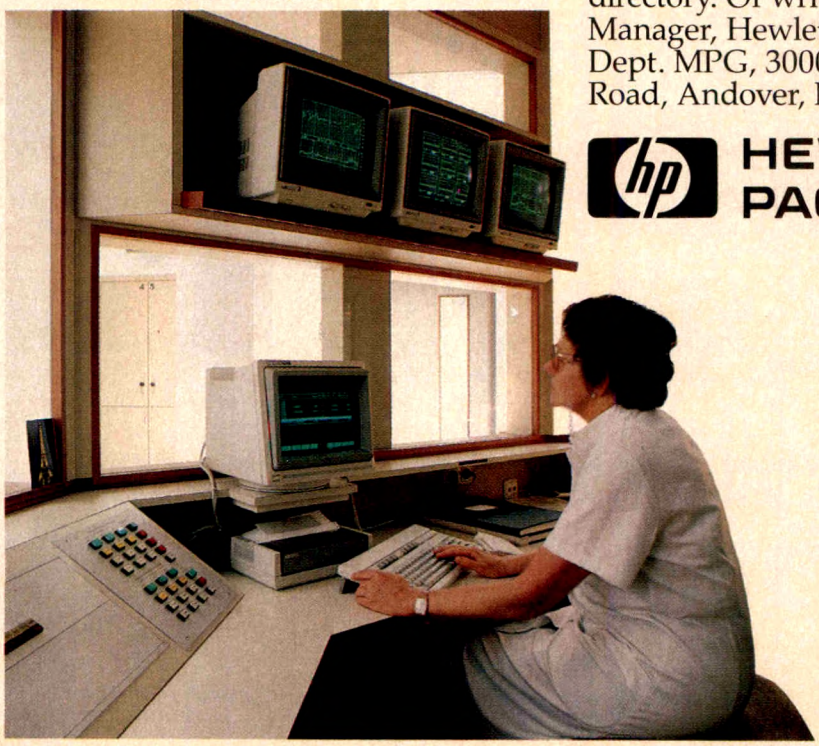


HP bedside fetal monitors: Guaranteed reliability.
HP bedside monitors deliver data with a reliability that's virtually unmatched. In fact, it's so dependable that we offer a *5 year* Guaranteed Performance Program.

Which is why OB professionals rely on the HP bedside fetal monitor—and why they can. Delivery after delivery, it provides accurate fetal heart rate and uterine activity data.

Obstetrical Management System: Improved patient care throughout the unit.
With the introduction of HP's Obstetrical Management System (OBMS), fetal trace records for up to nine patients can be viewed simultaneously on a single display for an immediate overview of all patients. The system also provides a close-up view of any individual traces at a central nurses station, allows you to store and print nurses notes, display a patient status "chalkboard," or visualize Friedmann curves.

Bradycardia and tachycardia heart rate limits, as well as limit delay times, can be set for each patient. And the system responds with visual and audible signals when the limits are reached—signals that come through strong and clear.



In addition, the OBMS also allows the nurse to access the overview screen from any patient's room, so that she can assess all patients from any bedside, as well as from the central station.

Fetal trace records for up to nine patients can be viewed simultaneously on a single display.

Bring Hewlett-Packard into *your* world.
To find out how you can bring all of the advantages of this new OB environment into your hospital, call your local HP sales office listed in the White Pages of your telephone directory. Or write: Inquiries Manager, Hewlett-Packard, Dept. MPG, 3000 Minuteman Road, Andover, MA 01810.

HEWLETT PACKARD

Now, the OB nurse can easily monitor several patients at once.

MG03608

SOME OF YOUR PATIENTS ARE ON DRUGS YOU DIDN'T PRESCRIBE.

An estimated 20 million Americans are using cocaine. Add to this the number of people using other illegal drugs and the total is truly staggering.

As a physician, you are in a unique position to help reduce this number.

Start with your next patient. While you are examining or treating her, simply ask about drug use. It *is* a medical problem. And knowing about it is the first step toward doing something about it.

Stop letting drugs be your patient's problem alone. *Look* for signs of drug abuse. And *listen* when you ask about patterns of drug use. What you hear could be a plea for help.

You'll never know unless you ask.

PARTNERSHIP FOR A DRUG-FREE AMERICA

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Zuspan is responsible for articles from the Society for Gynecologic Investigation. Manuscripts should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033. Dr. Quilligan is responsible for articles from The Society of Perinatal Obstetricians. Manuscripts should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Edi-

tor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

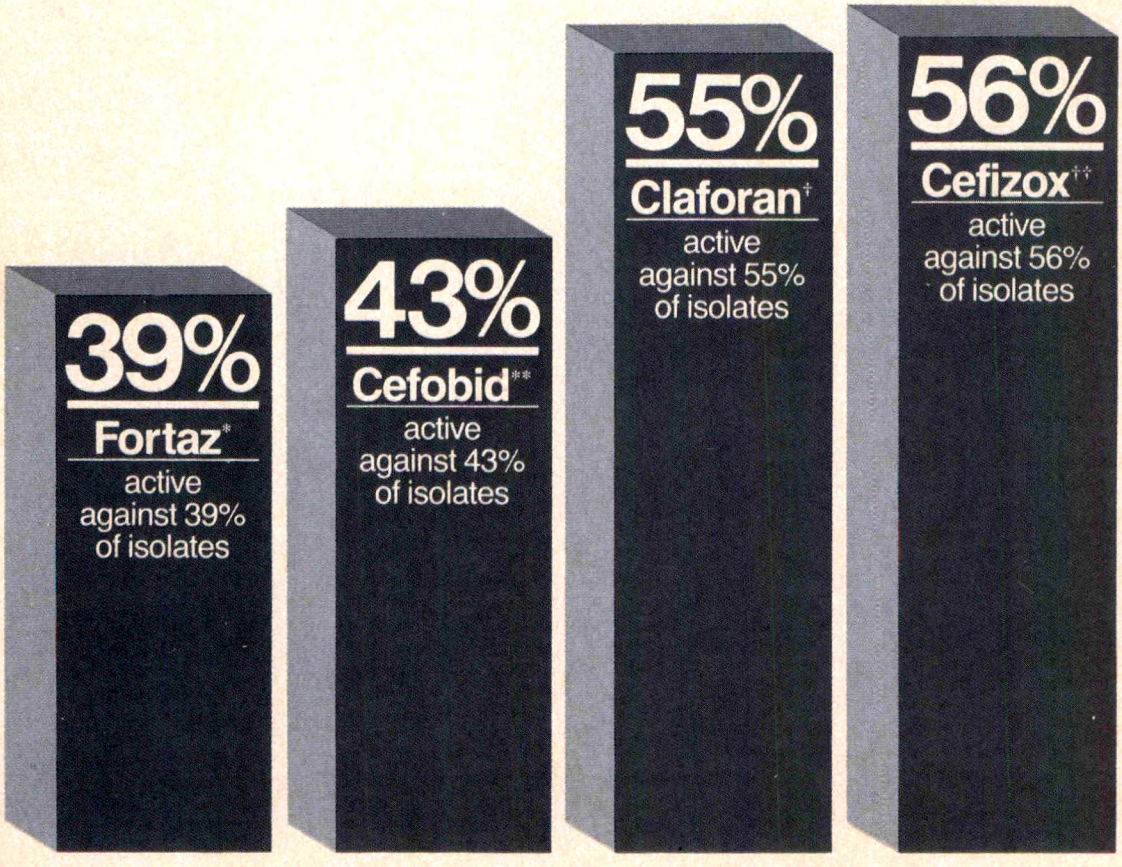
Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.



Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

Why settle for less activity

Don't Compromise

gainst the *B. fragilis* group?

94%
Mefoxin
active against 94% of isolates

the facts *still* favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus.*

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986,* Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST ‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage™# vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

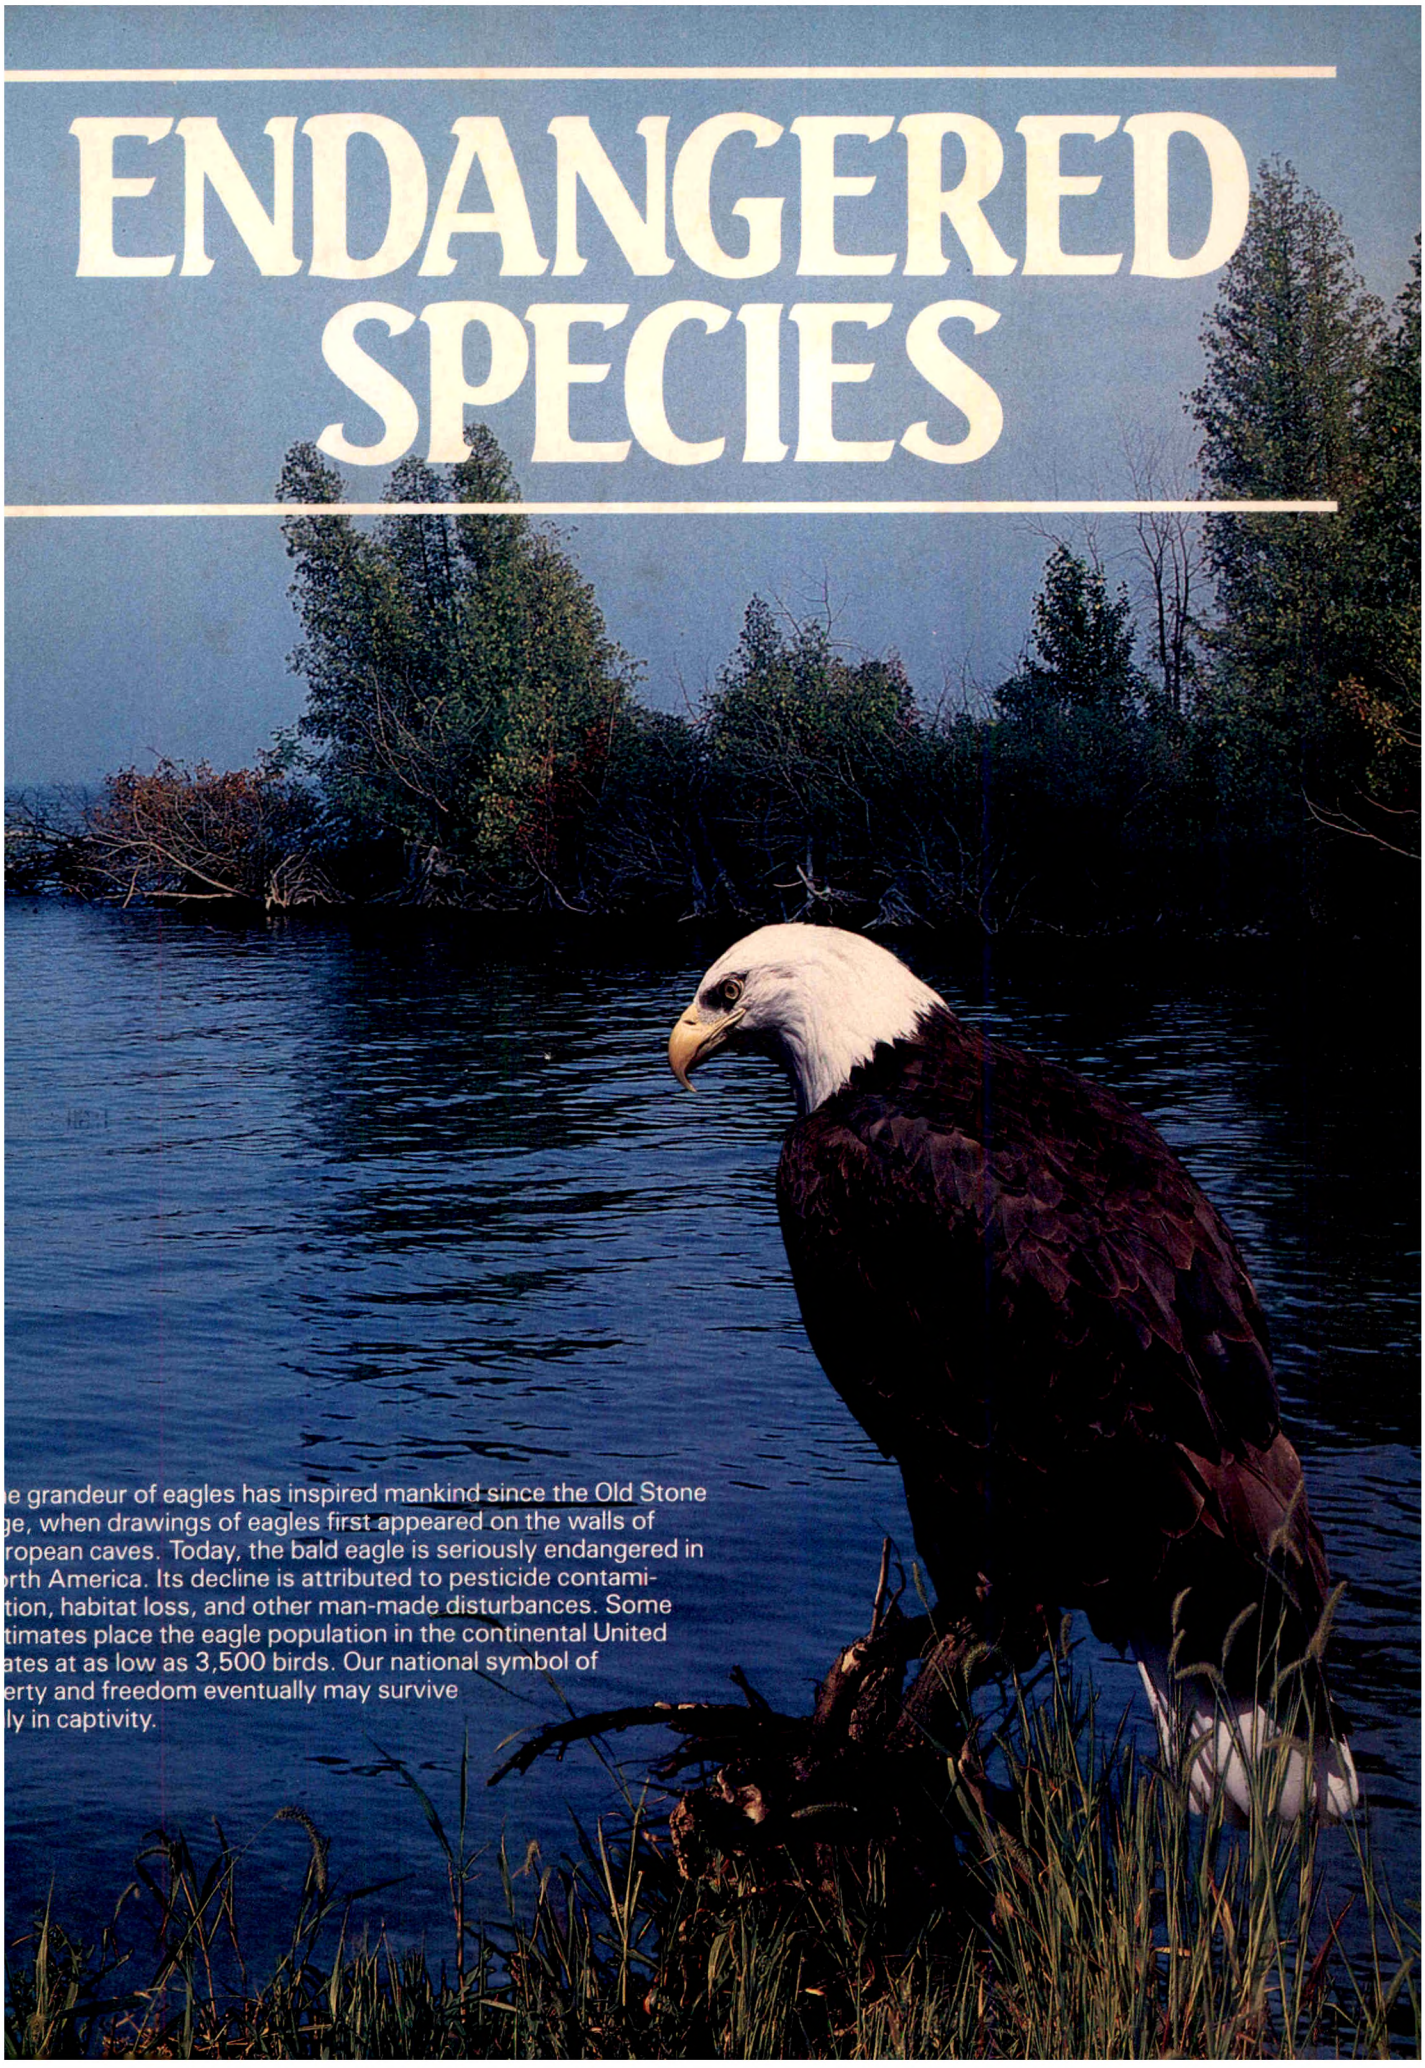
The Osteoporotic Syndrome, Second Edition
Detection, Prevention, and Treatment

Edited by
Louis Avioli, M.D.
Shoenberg Professor of Medicine, Department of Medicine
Director, Division of Bone and Mineral Metabolism
Washington University School of Medicine
The Jewish Hospital of St. Louis, St. Louis, Missouri

1987,192 pp., $18.50/ISBN: 0-8089-1859-1,Order Code: 790286



Combining new advances and information with the clear presentation of the first edition, **The Osteoporotic Syndrome, Second Edition** is a concise review of state-of-the-art techniques in the diagnosis, prevention, and therapy of the postmenopausal osteoporotic syndrome.

Like the previous edition, this text emphasizes a practical approach to the diagnosis and prevention of the osteoporotic process utilizing the most currently available knowledge. Physicians in the practice of internal medicine, orthopedic surgery, radiology, obstetrics and gynecology and rheumatology who are more apt to evaluate patients with the osteoporotic syndrome, will find this book particularly useful. Pathologists and medical or paramedical personnel in exercise physiology and nutritionists will appreciate the chapters on exercise, bone pathology, and the discussion of the role calcium plays in mitigating the potential complications of the osteoporotic problem.

Contents: Preface. Contributors. *L. Joseph Melton, III, and B. Lawrence Riggs*, Epidemiology of Age-related Fractures. *Charles H. Chesnut, III*, Noninvasive Methods of Measuring Bone Mass. *Steven L. Teitelbaum*, Osteoporosis and the Bone Biopsy. *Louis V. Avioli*, The Calcium Controversy and the RDA. *Robert P. Heaney*, Prevention of Osteoporotic Fracture in Women. *Robert Lindsay*, Estrogens in Prevention and Treatment of Osteoporosis. *Franz U. Steinberg*, Exercise in Prevention and Therapy of Osteoporosis. *Carlo Gennari and Louis V. Avioli*, Calcitonin Therapy in Osteoporosis. *Glenn Swogger, Jr.*, The Emotional Effects of the Osteoporotic Syndrome. *Linda Repa-Eschen*, Prevention and Treatment of Osteoporosis in a Healthcare Delivery System. Index.

ENDANGERED SPECIES

e grandeur of eagles has inspired mankind since the Old Stone
ge, when drawings of eagles first appeared on the walls of
ropean caves. Today, the bald eagle is seriously endangered in
rth America. Its decline is attributed to pesticide contami-
tion, habitat loss, and other man-made disturbances. Some
timates place the eagle population in the continental United
ates at as low as 3,500 birds. Our national symbol of
erty and freedom eventually may survive
ly in captivity.

ENDANGERED SPECIES?

Is the practice of obstetrics endangered? Its survival is threatened by factors that, if allowed to continue, are likely to diminish significantly the number of practicing obstetricians. The continuing increase in the number of malpractice lawsuits against physicians and the corresponding inflation of liability insurance premiums have plunged the obstetrics specialty into a crisis.

Patient-initiated litigation is now so common that 1 in 6 obstetrician/gynecologists is sued each year, compared with 1 in 20 only ten years ago. As a result, obstetricians pay three to four times more for malpractice insurance than do physicians in most other specialties.

Survival of the practice of obstetrics is further jeopardized because fewer students are entering the specialty and the number of experienced physicians leaving obstetrics or retiring early is on the rise. For many, this crisis has taken the joy out of practicing medicine.

HARVARD SYMPOSIUM: PRESERVATION THROUGH REFORM

Immediate action is essential to preserve the practice of obstetrics. In response to this need, G.D. Searle & Co. has organized the Searle Alliance for Health Care. This initiative is helping to lead a national effort to resolve the medical professional liability crisis.

A highlight of the Searle Alliance for Health Care program is a team comprised of experts in medicine, law, insurance, and public policy. These specialists will present recommendations and position papers about reform at a professional liability symposium to be held at Harvard University on October 9–10, 1987. Concerned leaders from a variety of fields will be in attendance to hear the proceedings and recommendations as the specialists consider effective routes to medical liability reform.

Cosponsored by Harvard's Division of Health Policy Research and Education and the Searle Alliance for Health Care, the symposium will be chaired by Kenneth Ryan, M.D., Chairman of the Department of Obstetrics and Gynecology at Harvard University School of Medicine.

Beyond the Harvard symposium, the Searle Alliance for Health Care has established a national campaign to help resolve the professional liability conflict and offers many local programs to help you deal with it.

For further information on the October 9–10 Harvard symposium or to view videotaped highlights of the proceedings, contact your Searle representative.

Demulen 1/35™

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

7A052T

Demulen 1/35™

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk*: Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems*: Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders*: In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction*: Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers	10.2	2.6		62.0	15.9
≥15 cigarettes daily	13.0	5.1		78.7	31.3
<15 cigarettes daily	4.7	0.9		28.6	5.7
Nonsmokers	1.8	1.2		10.7	7.4
Smokers and nonsmokers	5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases*: A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age:	<30	30-39	≥40
Heavy smokers (≥15/day)		C	B	A
Light smokers (<15/day)		D	C	B
Nonsmokers, no predispositions		D	C,D	C
Nonsmokers, with predispositions		C	C,B	B,A

Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions*: Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma*: Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycystic ovaries) occurred nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer with combination or progestogen-only OCs, though individual cases were reported. Studies show no increased breast cancer with OCs or estrogens. However, greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk of breast cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens rose and further increased with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other risk factors. Decrease in benign breast tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term users. Cervical microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increased cancer risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consider nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of breast cancer or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, etc.* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk, as was age over 30. Though benign, these lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk to duration of use, being much greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,000. Consider such lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to half with acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT may be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. OCs are contraindicated in case of past or present, benign or malignant liver tumors developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy, birth defects, malignancy in offspring*: Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in utero to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monitor such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DES-exposed daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Other estrogens may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL for vertebral, anal, cardiac, tracheoesophageal, renal, and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threatened abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, including OCs, during early pregnancy occurred in 18.2/1,000 births, compared to 7.8 for those unexposed ($P<.05$). More twinning was reported in conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but there is considerable evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased in abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion is increased soon after stopping OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not been demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods are missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. If pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy should use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not use progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years' use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydrate and lipid metabolism*: Decreased glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides and total phospholipids may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few months, and degree may relate to progestogen dose. Hypertension prevalence in users is not higher in the first year, but increases with longer exposure; in the 5th year it is 2½—3 times the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), preexisting renal disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Even though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors for cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache*: Onset or exacerbation of migraine or development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating cause. **10.** *Bleeding irregularities*: Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregular bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology is excluded, time or change to another product may suffice. Change to a higher-estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics*: In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be increased risk of ectopics after discontinuing. **12.** *Breast feeding*: OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after weaning. **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable difference in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC and troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask onset of climacteric. Cervical chlamydial prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients*. See patient labeling. *Drug interactions*. OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophen. **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic uremia, malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVCs, abnormal EKG, pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, and breast carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use and is available on request.**

TRANSACTIONS OF THE FORTY-NINTH ANNUAL MEETING OF THE SOUTH ATLANTIC ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Responsibility, obligation, and duty

Presidential address

Leo J. Dunn, M.D.

Richmond, Virginia

The opportunity to address one's colleagues in this manner on any topic that one regards important comes rarely. There are so many important matters that it is difficult to choose what thoughts one wishes to share. Having listened to presidential addresses in many organizations, I recognize that there is the opportunity to look backward on events that should not be forgotten or to stress current trends that are important to pursue or alter. Even more tempting is to predict the future. The latter I often call "highway speeches," perceiving the specialty to be at some "fork in the road" or "crossroads" where a vital decision needs to be made.

I have chosen today to speak of a current concern, one I believe that all members of this organization should share. My concern is the poor outcome of pregnancy that exists in our country and particularly that that exists in our own states. As obstetricians and gynecologists you know that the United States has a shameful record in our poor pregnancy outcome when compared with other developed countries. It is a source of national embarrassment that we are among the wealthiest of nations and yet our care of women and children, measured by perinatal, neonatal, and infant mortality rates, remains among the worst among comparable nations. We should be most concerned because the South has contributed most heavily to this poor record. Therefore I would like to present to you some data that will highlight the problem as I see it in the five states of the South Atlantic Association of Obstetricians and Gynecologists (i.e., Virginia, North Carolina, South Carolina, Georgia, and Florida). I have reviewed a great many data and have attempted to extract those data that will define the problem in a way that will point toward solutions and opportunities for our involvement. I have attempted to present the most recent complete data from our states. This has required using data for both 1983 and 1984.

I would like first to demonstrate that poor pregnancy outcome is indeed worse in our states than in the United States as a whole. Having demonstrated this, I would like to explore some of the characteristics of women who contribute heavily to poor pregnancy outcome so that we might better identify them, their unmet needs, and opportunities in which our intervention might be effective. I will attempt to prove that the most assailable common denominator of the factors that contribute to poor pregnancy outcome is unwanted pregnancies. I will particularly focus on the issue of teenage pregnancy as an important contributing cause that must be isolated for special attention. I will stress that inadequate sex education, inadequate contraceptive services, uneven access to abortion, and inadequate antepartum care are factors that contribute to the poor pregnancy results in our states. I would like to conclude with some recommendations that might be pursued by

From the Department of Obstetrics and Gynecology, Medical College of Virginia.

Presented at the Forty-ninth Annual Meeting of The South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 25-28, 1987.

all of us in our respective communities that would result in improvement of pregnancy outcome.

Fig. 1 illustrates that poor pregnancy outcome nationally is exceeded by each of our states in neonatal, perinatal, and infant mortality rates. Table I begins to offer some explanation for our poor outcome. The well-known fact that there is a marked difference between pregnancy outcome in white and nonwhite populations in this country is clearly demonstrated for the nation and for each of our states. Mortality rates in some cases are actually double for the nonwhite population. The importance of this for the South Atlantic states is the racial distribution of women of reproductive age in our states compared with the nation as a whole. It is clear that we have a much higher proportion of women at high risk for poor pregnancy outcome in our states. It is also clear to those who have toiled in this vineyard that the basic underlying factor is the relentless problem of poverty. The "war on poverty" in this country has not been won. Jones[1] of the Alan Guttmacher Institute compared the economically lowest 20% of the United States with that of other selected industrialized nations and stated that severe poverty continues in the United States whereas it has been alleviated in other nations. We as obstetricians and gynecologists can do little to reverse poverty in our states; therefore we must look for contributing factors on which we could have a positive influence.

There are certain patient characteristics that are recognized as high-risk factors in addition to race. Table II displays three of these: teenage pregnancy, incomplete education, and out-of-wedlock pregnancies. Once again, with few exceptions, our states exceed national averages for their occurrence. Exploration of these factors indicates that common among them is the issue of unwanted pregnancy.

In her tenure as President of the American College of Obstetricians and Gynecologists, a member of our society, Dr. Luella Klein,[2] was very forceful and vocal in her attempt to bring the issue of unwanted pregnancy before our specialty and the nation. Unwanted pregnancy is an enormous problem and one that is almost entirely preventable. Previous estimates have declared that >50% of the pregnancies that occur each year in the United States are unintended, many of which are unwanted.[1] In attempting to determine a rough estimate of the unwanted pregnancies in our states, I have used an artificial calculation you may criticize. However, I believe it gives a conservative estimate of unwanted pregnancies in our states. My calculation requires four basic assumptions. The first is that all pregnancies of married women are wanted. We know this to be untrue and the extent to which it is untrue makes the final calculation a conservative one. The second assumption is that all out-of-wedlock pregnancies are unwanted. This also has an error, but even in today's changed morality the probability of error is likely <10%, even for adults. The third assumption is that women who undergo voluntary induced abortion have unwanted pregnancies. The probability of error in this assumption seems small. Fourth is the assumption that spontaneous abortions occur with equal frequency whether the pregnancy is wanted or unwanted.

Based on these assumptions, my calculations in Table III indicate that between 40% and 47% of all pregnancies that occur in our states can be classified not only as unintended but as unwanted. If true, this indeed identifies an enormous problem that has serious health, social, economic, and emotional implications that affect more than a quarter of a million women each year in

our combined states. It most certainly must affect the individuals born of these pregnancies for a lifetime. Although unwanted pregnancy is an issue for all races and all ages of women, Tables IV and V demonstrate the particular preponderance of this problem for black women and adolescents.

No national or regional statistics characterize pregnancies in their outcome by whether they are wanted or unwanted. Therefore, to demonstrate that unwanted pregnancy is indeed related to poor pregnancy outcome, I have looked at outcome that is related to those factors that I believe identify them. We must look at pregnancy outcome in the very young in whom out-of-wedlock pregnancy rates are very high and in whom abortions are very frequent. We must also look at the pregnancy outcome in nonwhite women as compared with white women. As McCormick[3] has emphasized, the most important determinant of neonatal, perinatal, and infant deaths is that of low birth weight. Therefore I have chosen this as my indicator because it will include both morbidity and mortality rates. Births of infants of low weight are, in fact, the most important challenge in current obstetrics because its prevention must be achieved if pregnancy outcome is to be improved. In

Figs. 2 and 3, using national data, I have demonstrated the relationship between maternal age and the occurrence of both low birth weight and very low birth weight infants. I have superimposed the incidence of out-of-wedlock pregnancy over this age range. The relationships here seem very clear. In Fig. 4 I have simply recorded the occurrence of live births of low birth weight, separated by race, in each of our states and compared them with national figures. Once again is demonstrated the influence of race and the poor outcome in our states compared with that of the whole country. I believe these figures support the claim that those factors identified as defining unwanted pregnancy are related to both low birth weight and poor pregnancy outcome. Although it is not the entire solution to the problem I would like to predict that a strong and concerted effort in our states to prevent unwanted pregnancy, if successful, would have a profound effect on pregnancy outcome within a relatively short period of time.

I stated initially that I wanted to focus specifically on the issue of teenage pregnancy. Although teenage pregnancy does not represent the majority of unwanted pregnancies, the high percentage of unwanted pregnancies and the relatively tragic aspect of teenage pregnancy demands that we pay special attention to this issue. Prevention of teenage pregnancy is clearly a major public health issue, not only for our region but for the United States as a whole. Although it is neither a realistic nor necessarily desirable goal, the prevention of pregnancy in women 19 years of age or younger would reduce births of low weight in this country by 18% and by a higher percentage in our region. There are a number of myths in regard to teenage pregnancy that are important to dispel. There is a common belief that these women and disadvantaged women of all ages deliberately undergo pregnancy because of financial rewards of public assistance programs, etc. The study of Jones[1] from the Alan Guttmacher Institute in 1985 showed clearly that such financial advantages are fewer

American teens speak: sex, myths, T.V., and birth control. The Planned Parenthood Poll, Project No 864012. Louis Harris and Associates, Inc., October 1986.

in the United States when compared with those of other nations of comparable economic level and with fewer teenage pregnancies.[1] It is also commonly stated that many of these children become pregnant because they have no ambitions for personal success or see no such opportunities. A recent Planned Parenthood survey dispels that myth by demonstrating that 94% of all teenagers have high personal aspirations that clearly will be thwarted by unwanted pregnancy.[4] It is important to recognize the severe damage that unwanted pregnancy does to the lives of these young individuals. Half of these women will never complete their education and many will be forced to live the rest of their lives in poverty because early childbearing has limited their opportunities.[5] This entrapment of our youth by unwanted pregnancy is indeed an American tragedy that contributes to many societal ills such as poverty, welfare dependence, and child abuse.

Fig. 5 taken from the Jones study[1] dramatically demonstrated that the United States has a dismal record of teenage pregnancy when compared with other industrialized modern nations. Notice that there are as many or more abortions among teenagers in our country than there are pregnancies in teenagers of nations with whom we were compared. Jones also demonstrated that this is not simply a racial issue because the pregnancy rate among white American teenagers alone exceeded that of teenagers in all the other nations with which they were compared. It is not true that teenagers in our country are more sexually active than those in other nations because their study showed that our adolescents are at the mean for all of these countries in sexual activity. The important difference is clearly in the prevention of pregnancy. Unwanted pregnancy is a sexually transmitted disease and prevention must be achieved.

Prevention of teenage pregnancy has been approached in other nations by strong educational programs linked with contraceptive services and abortion available for management of the failures. This was achieved in these other nations by the public consensus of a need to solve a critical national problem. In our country, because of the influence of diverse groups who become involved in public debate, we are chronically unable to develop a public policy or an organized approach to solve our problem. Therefore a national solution to this problem never will be forthcoming, in my opinion. It is of vital importance that state and local solutions be developed and it is in this arena that we can be effective.

Analysis of public school sex education programs in metropolitan areas has indicated that only 34% of these are rated as comprehensive.[6] Dr. Koop and Secretary Bennett will need to present their thoughts more clearly if I am to be convinced that sex education in our schools is important and appropriate to prevent acquired immunodeficiency syndrome but not to prevent pregnancy. This dilemma was clearly demonstrated in our community in the past month in which the reports of the Planned Parenthood Survey and Dr. Koop's recommendations were countered by editorials expressing skepticism about sex education in the schools.[7, 7a] Little progress has been made in spite of the fact that the majority of the public support such education. Public debate in this country is not focused on the problem but only on the solutions. Very vocal groups insist that solutions be limited to the prevention of premarital sex and no other solution is acceptable. I agree that teaching children not to play with matches is appropriate. However, when the house is on fire a lecture on playing with matches is neither effective nor appropriate. This house is on fire.

Good comprehensive sex education begun early enough is not likely to increase teenage sexual activity but will help in preventing unwanted pregnancy.[8] Because our school system has repeatedly failed to accomplish this, perhaps we as obstetricians and gynecologists can be helpful in this arena in our communities. It has been stated that teenagers in the United States are learning sexual behavior by seeing >9000 sexual events on television each year. None of these events address the issues of responsibility or contraception. At present both the American College of Obstetricians and Gynecologists and Planned Parenthood are trying to reverse existing network policies against contraceptive information. Planned Parenthood is currently asking for our support in appealing to the networks to change this policy and I would advocate that each of us support this effort vocally and financially. Consumers can also support this effort very effectively if they would be informed as to the sponsors of the programs that promote unbalanced information. My second recommendation in regard to education is that the American College of Obstetricians and Gynecologists be petitioned to develop more sex education material that can be used by us, other health professionals, educators, parents, or the individual himself or herself. The American College of Obstetricians and Gynecologists recently produced an excellent educational tape on physical exercise for home use to improve women's health. Could they not produce similar material on sex education using a medium attractive to our teenagers? Could they develop seminars for those willing and qualified to be educators in our communities? I believe that this would be an important educational endeavor and a method by which the misinformation held by the public in regard to contraception such as the fear of carcinogenesis could be dispelled and corrected.[10] Working in concert with national, regional, and local organizations that are already pursuing these goals, you and I could play an important role in improving sex education, especially for this vulnerable group. Such educational programs can be devised to improve self-esteem, alter what is considered normative behavior, establish a sense of responsibility, and provide the knowledge necessary to avoid pregnancy and disease.

The second area of my concern is in regard to contraceptive services. It has been shown that if sex education is not linked to the availability of contraceptive services it is far less effective. The nature of the problem can be better defined by first showing the degree of sexual activity of our teenagers at the present time. Fig. 6 shows the latest available figures from a 1986 Planned Parenthood poll conducted by Louis Harris and Associates.[4] You can see from these figures that involvement in sex begins at a very early age with 7% of girls being sexually active at the age of 12 years. Before the age of 17 years more than half of both boys and girls have engaged in sexual intercourse. Fig. 7 indicates the interval between first intercourse and conception in 18 and 19 year olds.[11] Considering adolescents of all ages, Dryfoos[12] has stated that one third become pregnant within the first 24 months regardless of the age of onset of intercourse. Surveys have demonstrated that on the average a teenager will be sexually active for >16 months before she seeks help with contraception from available clinics.[13] Therefore, recognizing the early age of sexual activity and long delay before seeking contraceptive services, it is evident that to be effective sex education must be early and linked to provision of contraceptive services. The most effective way to accomplish this is to provide such clinics in the public schools. Your voice in your local community school board meetings presenting the information I have outlined today, with your recommendation that this is an important solution to the problem, would be

Table VI. Live births and induced abortions by age in Virginia, 1983

very influential. If the obstetric and gynecologic society in your community, as a body, addressed the school board with such recommendations and the willingness to voluntarity participate as teachers and providers, it could hardly be ignored. I know of no instance in which an obstetric-gynecologic society has made such a direct request to any school board.

Teenagers have specific needs for contraceptive services that are not being met. Teenagers require direction toward these services; their self-motivation is not sufficient. They are neither knowledgeable nor adept at accessing health care for themselves. Impediments must be recognized and removed. The services must be readily available and this is why I advocate school clinics as the ideal for the 75% of teenagers who are enrolled in school. Community contraceptive clinics that are open only while teenagers are in school are inaccessible. For the other 25% and for those communities in which the schools will continue to reject recommendation for such clinics, neighborhood clinics or physician's offices would be the alternatives. It is very important that these services be confidential wherever they are provided. Parental consent requirements interfere with women's willingness to seek help and the physician's willingness to prescribe.[14] Recognize that as parents you do not discuss your sexual practices with either your parents or your children. Expecting otherwise from teenagers is unrealistic. State laws authorizing minors to give their own consent increase both patient and physician participation.

Services provided must be inexpensive or free. The usual and customary rates for office visits and oral contraceptives are out of the financial reach of most of these young people. State budgets for contraception rely too heavily on federal sources and too little on state resources to meet the needs.[15] Oral contraceptives should be made available by the state at low cost to teenagers whether the individual receives her prescription from a clinic or a private physician. The requirement for pelvic examination before the prescription of oral contraceptives is stated to be a deterrent by 69% of teenagers.[4] Although it will be controversial, I believe it is important for our specialty to further evaluate the risk versus benefit of pelvic examination for the initiation of oral contraception for the young teenage woman. Elimination of this requirement would increase the use of effective oral contraception by the young teenager, and the risks versus benefits of this approach should be seriously reconsidered.

Therefore, we as obstetricians and gynecologists can be effective in providing contraceptive education and contraceptive services by our individual efforts, through our societies, through local school boards, in concert with Planned Parenthood, and through public health clinics, by providing services on a voluntary basis. Although many nonmedical civic-minded individuals are making efforts toward the prevention of pregnancy, only you and I are legally able to prescribe the most effective forms of contraception, and therefore we have a responsibility to participate.

Even under ideal circumstances contraceptive failures occur. In her Presidental Address to the American College of Obstetricians and Gynecologists, Dr. Klein[2] emphasized this fact and the role of abortion for these unwanted pregnancies. Induced abortion has been determined as a legal right of women in this country but remains a controversial and divisive issue. I have already demonstrated the relatively higher use of abortion in teenagers as compared with other age groups. This is further demonstrated in Table VI giving information from the state of Virginia on the relative use of induced abortion by age groups for 1983. One might imply from these figures that abortion is readily available to these individuals. However, Fig. 8 demonstrates the proportion of out-of-wedlock pregnancies by outcome and age group for the same state during the same period. This information casts a different light on the issue. One can see that the decision-making process for continuation of an out-of-wedlock pregnancy or the use of induced abortion varies markedly by the individual's age. Freedom of choice and accessibility of services may indeed be related to the individual's ability to act with independence. The Supreme Court ruled that access to induced abortion is a woman's right. Subsequent actions by federal and state legislators have denied access to induced abortion for the underprivileged by the economic maneuver of denying public funds for these procedures. Therefore, in the United States today the individual who has the least access to abortion services is the very young, black teenager with an out-of-wed-

lock pregnancy. By some distortion of thinking this is considered constitutionally correct and in keeping with democratic principles.

Most of you belong to medical organizations that have lobbying services at state and federal levels and to which you contribute regularly. One of the strongest lobbies in the United States today is that of the medical profession. If they are to have credibility, these lobbies must be used not only for the good of the profession but also for the public good. If you have the conviction that we must solve the issue of unwanted pregnancy to improve the outcome of pregnancy, you must make provision of contraception and the provision of abortion services an issue in your state. Through these lobbying mechanisms we can insist on the legislative changes that would make these services accessible to the needy but disenfranchised. Using our lobbying efforts only for purposes of our own self-interest weakens our credibility when we turn to the public for their support for issues such as the current malpractice controversy. Perhaps the lack of public concern about our malpractice dilemma is a reflection of their perception of our lack of concern for the public in issues such as the one I am bringing before you today. If we are clearly an advocate of the public's welfare I believe they will more clearly be an advocate of ours.

I would like to turn away from these comments regarding prevention of pregnancy to address those pregnancies that do continue to delivery. It is clear that socially and economically disadvantaged pregnant women have a worsened pregnancy outcome. Several studies including those of Peoples and Siegel[16] and Showstack et al.[17] have demonstrated that inadequate antenatal care is an important contributing factor to the birth of low birth weight infants. Table VII shows that in our states we have made important progress in providing hospital delivery services for almost all women. It also demonstrates that almost all births are attended by physicians. Our continued weakness is in the provision of antenatal care. Fig. 9 indicates that nationally and locally we have an unacceptable number of women who receive no prenatal care or late prenatal

care. If the American College of Obstetricians and Gynecologists' standards of number of prenatal visits were applied, the percentage of inadequate antenatal care is even higher. Surely the provision of obstetric care must be regarded as a key responsibility of the obstetrician/gynecologist.

We do not have a severe manpower shortage in obstetrics and gynecology in the South Atlantic states. Table VIII demonstrates the ratio of obstetric practitioners to live births in our states giving both those listed by the American College of Obstetricians and Gynecologists as fellows and those listed by the American Medical Association as doing any obstetric practice. The figures of the American College of Obstetricians and Gynecologists also include some residents-in-training who are registered as junior fellows. Table IX addresses the issue of whether there is a need for practitioners versus residents to participate in the care of medically indigent patients. There seems to be a growing concept that such patients should be relegated to hospitals that have residency training programs "for the good of the residents." Because data are not available on medically indigent obstetric patients, I have taken as an assumption that the out-of-wedlock pregnancies in our states would constitute the majority of those patients who are medically indigent. This is at best an approximation but demonstrates that it is not reasonable to expect our residency training programs to assume responsibility for the entire indigent obstetric population. Therefore, it continues to be necessary that the practitioner of obstetrics and gynecology participate in their care.

Many of us willingly and voluntarily participate in the provision of health services to the medically indigent. When I arrived in Virginia 20 years ago a Public Health survey indicated that the average obstetrician/gynecologist spent 17% of his or her time providing services to the poor. Indeed that has continued in many of our communities in which physicians I know have given up to as much as one third of their time in the provision of services to the community's needy. I agree that this voluntary provision of services has not been given sufficient public recognition, and our practitioners have received little or no credit for these services in the past. My concern is that this volunteerism and sense of responsibility is becoming altered, distorted, and now avoided in many communities. Newspapers report increasing incidents of community physicians and community hospitals refusing care to indigent obstetric patients. In prior years in our community, many of the leading obstetricians and gynecologists were seen regularly in our public clinics and inpatient services for purposes of teaching and giving service. Today in our community, with few notable exceptions, the leading obstetricians and gynecologists in our community are never seen giving such public service. Both proprietary and community hospitals ma-

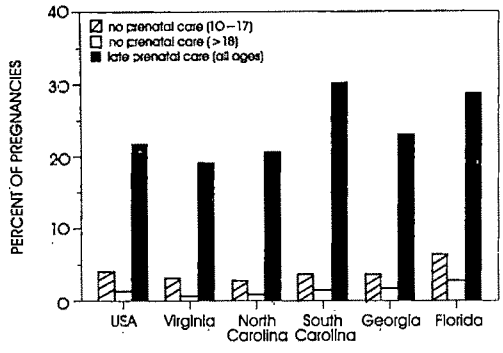

Fig. 9. Comparison of inadequate prenatal care in the South Atlantic states with that occurring in the United States in 1984. *Source:* RNDMU Region IV, 1986, and Virginia 1984 Vital Statistics Report. Richmond, Virginia: Center for Health Statistics, Virginia Department of Health.

nipulate in every way possible to avoid providing care to these medically needy patients. The stated reason for this change among our practitioners and their hospitals is the malpractice climate. It is alleged that the indigent population is more litigious than other segments of our society. It is declared manifestly unfair both to provide free care and to be at risk for litigation for doing so. Although I do not question the unfairness of this situation, I do wish to express doubt that this group of individuals are indeed more litigious than any other segment of our population. I feel that this issue should be studied and predict that the outcome will prove that they are not. However, the unfairness issue is valid and needs to be addressed. My recommendation is that obstetricians and gynecologists, through their appropriate medical societies, recommend legislation in their states to apply "good samaritan" rules to physicians who provide free medical services to the needy and make it an obligation of the state to indemnify physicians for these charitable acts. Such legislation is under serious consideration for submission to the state legislation in Virginia this year. If these two things can be accomplished, I would hope with that reassurance that every practitioner of obstetrics and gynecology would accept as a personal responsibility the contribution of free service to the medically needy obstetric patient. This has been a tradition in our specialty that is becoming distorted in an unattractive way by both malpractice and commercial competition that are reshaping our profession in ways that we must resist.

What I have attempted to do in this short time is to bring to your attention as obstetricians and gynecologists that there continues to be a significant problem of quality of reproductive outcome in the states in which we live and practice. I have tried to put forth the argument that a basic cause of this poor outcome derives from the high numbers of unwanted pregnancies that occur in our states. Reduction in the rates of these

unwanted pregnancies requires our intervention at various levels.[11] I must justify the reason for bringing these matters and these recommendations to the attention of the South Atlantic Association of Obstetricians and Gynecologists. My belief is that this society is composed of individuals invited into its membership on the basis of being an outstanding obstetrician/gynecologist in his or her state. This is a society that presumably represents the elite practitioners, teachers, and researchers of obstetrics and gynecology in our five states. If I have represented to you correctly that the problem of the outcome of pregnancy in our states is the most important health problem related to women under our care, I believe it is an issue important for this society to discuss and determine in what ways it can affect change. I must express the opinion that we have not provided leadership in the effort to solve this critical problem. The way has already been paved by such organizations as Planned Parenthood, the Guttmacher Institute, the March of Dimes, the Southern Governors Regional Task Force on Infant Mortality, Healthy Mothers, Healthy Babies Coalition, and others. Recent efforts on the part of Nurses Association of the American College of Obstetricians and Gynecologists and American College of Obstetricians and Gynecologists such as the establishment of standing committees on underserved women and adolescent care will direct our national involvement, but you and I must attempt to solve the problem at the local level. For example, the concern by the governors of our states has led to new provisions in the federal Medicaid Law that would specifically allow pregnancy care for the many women who now have no support. Concerned groups in our states who recognize the value of antepartum care are lobbying actively in behalf of these women to urge the state legislators to adopt the program. Few obstetricians are even aware of this important legislation and state obstetric/gynecologic societies in the South Atlantic states are too engrossed in issues of tort reform to lobby in favor of it.

In my view effectiveness in bringing about change will require a coordination of efforts of our various professional societies together with the efforts of those organizations that have expressed concern and already made efforts to improve pregnancy outcome. The South Atlantic Association is a society of considerable prestige and influence in our five states. It is composed of you outstanding men and women to whom society has given the right to practice obstetrics and gynecology in a setting of your choice with substantial economic reward. John D. Rockefeller stated in 1941 "I believe that every right implies a responsibility; every opportunity, an obligation; every possession a duty." I can only express my hope to you that the President of the South Atlantic Association at the end of this century will choose for his or her address to look backward and will be able to report with pride our achievements in improved outcome of pregnancy.

I appreciate Rae Grad of the Southern Governors' Association, Judy Fielden of the American College of Obstetricians and Gynecologists, Beverly Derr of the Statistics Bureau of the Virginia State Health Department, and Cathy McCray of the Medical College of Virginia for their assistance in obtaining the data presented here.

A prospective comparative study of the extended nonstress test and the nipple stimulation contraction stress test

Lawrence D. Devoe, M.D., John Morrison, M.D., James Martin, Jr., M.D., Sue Palmer, M.D., Rick Martin, M.D., Nancy Searle, B.A., and Martha Arthur, R.N., B.S.N.

Augusta, Georgia, and Jackson, Mississippi

The nonstress test and the nipple stimulation contraction stress test were performed at the Medical College of Georgia and the University of Mississippi Medical Center, with the use of common maternal state protocols, minimum criteria for baseline fetal heart rate reactivity, and follow-up of abnormal test results. At the Medical College of Georgia, 656 patients were studied with nonstress tests used as the primary test, whereas at the University of Mississippi Medical Center, 614 patients were managed with the nipple stimulation contraction stress stest used as the primary test. Both populations were comparable in regard to pregnancy complications, gestational age, birth weight, perinatal outcomes, cesarean section rates, and the incidence of positive contraction stress tests. Specificity and positive and negative predictive values were similar for both tests. The extended nonstress test had higher sensitivity but also required significantly longer mean duration of testing. The corrected perinatal mortality rate for a reactive nonstress test or negative nipple stimulation contraction stress test was zero within one week of the last test. We conclude that both tests provide excellent primary methods of fetal surveillance and that the decision to use one test rather than the other should be made on the basis of considerations of cost, convenience, time availability, and the presence of specific test contraindications or pregnancy complications. (Am J Obstet Gynecol 1987;157:531-7.)

Key words: Nonstress test, nipple stimulation contraction stress test

During the past decade, antepartum fetal heart rate (FHR) testing has become a principal method of fetal assessment. FHR testing uses two primary approaches, the contraction stress test (CST) and the nonstress test (NST).[1-5] More recently, there has been a trend toward performing the CST by intermittent nipple stimulation (nipple stimulation CST) rather than by the infusion of exogenous oxytocin.[6, 7] Since the inception of both FHR tests, there has been controversy over which test provides better primary evaluation of fetal well-being. One major study, involving 18 institutions during a 4-year period, concluded that the CST was the better primary test.[8] However, this report was flawed in several respects: (1) the individual obstetric features of each study population were not specified; (2) uniform criteria for NST reactivity were not employed; (3) a disproportionate number of patients were studied with CSTs; (4) clinical responses to abnormal test results were not presented; and (5) the NST group had a higher rate of low birth weight infants. In view of these problems, and the increasing popularity of the nipple stimulation CST, we undertook the present study to compare the diagnostic values of the NST and nipple stimulation CST in two comparable obstetric populations, by means of a uniform baseline testing protocol and similar minimum criteria for reactivity.

Material and methods

During an 18-month period, 1270 high-risk obstetric patients were tested at the Medical College of Georgia and the University of Mississippi Medical Center. A common maternal testing protocol was adopted (Table I), incorporating the same minimum criteria for reactivity. At the Medical College of Georgia, all fetuses were tested, with a previously reported NST scheme[9] in which a 30-minute baseline level was established. If at least three accelerations of 15 beats/min and 15 seconds' duration were not present, testing was extended by 30-minute increments until these criteria were met or 90 minutes had elapsed. Any test not producing a 30-minute reactive window was considered nonreactive. An NST was deemed unsatisfactory if a continuous 30-minute recording acceptable for interpretation could not be obtained. Nonreactive 90-minute NSTs were followed by oxytocin-stimulated CSTs (Fig. 1).

At the University of Mississippi Medical Center, the nipple stimulation CST was used as the primary testing

method and was performed according to the technique of Huddleston et al.[6] During the baseline period of 30 minutes an NST, with the same minimum criteria used for reactivity as at the Medical College of Georgia, was performed in conjunction with nipple stimulation CST when sufficient uterine activity was not present to perform a spontaneous CST. During this period, the CST by nipple stimulation or by spontaneous contractions was conducted (while the response to fetal movements was monitored). The assessment of fetal reactivity, if not initially present, was continued for at least 30 minutes in each case whether or not uterine activity was elicited. A nipple stimulation CST was considered satisfactory once an interpretable FHR pattern with at least three adequate contractions every 10 minutes was achieved. A nipple stimulation CST was unsatisfactory if an adequate contraction pattern could not be achieved in 30 minutes. Hyperstimulation was defined

as the occurrence of uterine tetany or tachysystole. A nipple stimulation CST was positive if late decelerations occurred with at least 50% of contractions, negative if no late or variable decelerations occurred, and equivocal if occasional late or variable decelerations were present. Clinical management of the various test outcomes is presented in Fig. 1.

Perinatal outcomes, chosen as end points in this study, included death, intrapartum fetal distress, 5 minute Apgar scores, intrauterine growth retardation, and postmaturity syndrome. Correlations of perinatal outcome and test results considered only patients delivered within the week of their last test and were based on the last test before delivery. Diagnostic parameters of sensitivity, specificity, predictive value, and prevalence are defined in Table II. For purposes of comparison, positive CSTs and persistently equivocal CSTs were grouped together because their clinical management was the same. Statistical comparisons used t tests, z tests for significant differences between two proportions, χ^2 tests, and the receiver operating characteristic curve[10] where appropriate.

Results

Test populations. A total of 1270 patients undergoing 3061 FHR tests were studied at the two institutions. Primary test indications are listed in Table III and were similar in both groups. Perinatal outcomes of each testing group are compared in Table IV and were similar for each end point.

Test results and perinatal outcomes. Table V compares the NST and nipple stimulation CST results. Both groups were similar for the total number of tests, the mean number of tests per patient, the proportion of patients delivered within 7 days of their last test, and the percentage of patients having abnormal CSTs. The NST group required significantly more time per test than the nipple stimulation CST group (36.4 versus 31.0 minutes), whereas the nipple stimulation CST group had a significantly greater proportion of nonreactive tests.

The associations of perinatal outcomes and test results are summarized in Table VI. There were no significant differences for any of the major outcome categories when reactive NSTs (Medical College of Geor-

Sensitivity: $\frac{33}{69}$ versus $\frac{20}{67}$; $z = 2.17$; $p = 0.03$.

Specificity: $\frac{541}{544}$ versus $\frac{510}{515}$; $z = 0.728$; $p = 0.46$.

Positive predictive value: $\frac{33}{36}$ versus $\frac{20}{25}$; $z = 0.869$; $p = 0.30$.

Negative predictive value: $\frac{541}{577}$ versus $\frac{510}{557}$; $z = -0.855$; $p = 0.39$.

Prevalence: $\frac{69}{613}$ versus $\frac{67}{582}$; $z = -0.109$; $p = 0.91$.

gia) were compared with negative nipple stimulation CST (University of Mississippi Medical Center) or when nonreactive NSTs (Medical College of Georgia) were compared with positive nipple stimulation CST (University of Mississippi Medical Center) (Table VII). Incidence of bad outcomes was virtually identical in both groups (NST, 11.3%; nipple stimulation CST, 11.5%; $z = -1.09$; $p = 0.91$). Although the NST group had higher sensitivity, specificity, and predictive values, only the differences in test sensitivity proved to be significant by z tests. The receiver operating characteristic curve is another means of evaluating diagnostic tests.[10] The plots derived from both study groups are shown in Fig. 2 and reveal that both fall along the ideal line for diagnostic tests.

There were four perinatal deaths in each group. In the NST group, there was one antepartum death. This occurred after nonreactive NST, which was followed by equivocal results of a CST given to an infant with severe growth retardation at 35 weeks' gestational age. A repeat test was planned for the next day; however, the patient failed to keep her appointment and returned 6 days later with an intrauterine fetal death. Three neonatal deaths occurred in the NST group: one after a nonreactive NST and positive CST in an extremely premature infant weighing 660 gm and two after reactive NSTs (abruptio placentae with perinatal asphyxia and renal dysplasia with neonatal renal failure). In the nipple stimulation CST group, there were two antepartum deaths: one after a negative CST resulting from abruptio placentae and one after a reactive positive CST associated with intrauterine growth retardation. Both neonatal deaths in this group occurred after nonreactive positive CSTs: one with extreme prematurity (weighing 704 gm) and the other after meconium aspiration syndrome in a growth-retarded fetus. None of the perinatal deaths occurring after normal tests (reactive NST or negative CST) could be considered preventable.

Perinatal morbidity was similar in both groups for both reactive NSTs and negative CSTs. In the NST group, 9 of 34 cases could be considered nonpreventable or nonpredictable as they were either consequences of intrapartum accidents or of prematurity. In the nipple stimulation CST group, 11 of 41 cases could be considered nonpreventable or nonpredictable for the same reasons.

Comment

This is the first prospective study comparing the efficacy of the NST with that of the nipple stimulation CST. Unlike the earlier multi-institutional report,[8] we used a standardized maternal state protocol, a uniform initial baseline interval, and common minimum criteria for reactivity. Moreover, both study groups had similar testing indications, obstetric characteristics, and perinatal outcomes. Finally, abnormal test results led to active intervention, usually resulting in delivery within the next 24 hours.

With the use of the same exclusion criteria as those of Freeman et al.,[8] there were no perinatal deaths in our study groups after either a reactive NST or negative nipple stimulation CST. The prevalence of bad outcomes, test specificity, and predictive values was similar for both testing schemes when all major perinatal complications were considered. Test sensitivity was somewhat greater in the NST group, even when corrected for nonpreventable bad outcomes. Although this difference between the two groups was significant, in neither group did test sensitivity exceed 50%. The differences in the incidences of nonreactive tests (Table V) could be explained by the fact that the Medical College of Georgia patients with initially nonreactive 30-minute tests had their sessions extended by 30-minute increments, with those in the University of Mississippi Medical Center group completing their testing in 30 minutes if the nipple stimulation CST was negative whether or not reactivity had been achieved. As reported earlier,[11] a 30-minute FHR baseline NST is associated with a "false" nonreactivity rate in 16% of normal fetuses. Therefore, this difference probably reflects the effect of increased observation time in the Medical College of Georgia group. Conversely, the incidence of positive or persistently equivocal CSTs was quite similar in both groups, suggesting that the extended NST is an effec-

There were fetuses in each group with more than one perinatal complication.

Comparisons of reactive NST versus negative CST and nonreactive NST versus positive CST revealed no significant differences by Fisher's exact test.

tive screening tool for those fetuses requiring further evaluation although the mean length of testing is significantly greater. Finally, the utility of both tests could be examined by comparing those fetuses for whom the initial test provided satisfactory data for assessment. In the nipple stimulation CST group, hyperstimulation was uncommon (28 of 1495 tests), comparing favorably with that reported for the oxytocin CST,[4] whereas 36 tests (2.4%) required exogenous oxytocin. This gave an overall incidence of 4.3% of tests that could not be used for immediate assessment and that necessitated repeated testing later the same day. There were also 75 nipple stimulation CSTs that were initially unsatisfactory, requiring repeat testing sessions. In contrast, there were only 20 of 1566 NSTs (1.3%) that were unsatisfactory at 30 minutes; 10 remained unsatisfactory at 60 minutes; and three were unsatisfactory at 90 minutes.

Antenatal FHR testing, whether by CST or NST, has resulted in reduced rates of perinatal death.[12] Neither method has been clearly shown to provide superior primary fetal surveillance because previous studies have either lacked sufficient numbers for comparison or have not used uniform testing conditions, interpretative criteria, or patient follow-up. The experience of these two high-risk referral centers suggests that the decision to employ one test rather than the other should be made on the basis of specific considerations. These include (1) contraindications to the CST, for example, third-trimester bleeding, (2) fetal risk not related to uteroplacental insufficiency, for example, malformations, (3) gestational age at which uterine insensitivity to oxytocin may preclude a satisfactory CST or at which reactivity criteria are not well established, and (4) cases in which cord vulnerability is suspected, for example, oligohydramnios. A further consideration that may influence test selection is that extending the NST increases the mean length of testing periods and personnel time. This may over time reduce the testing capability of a large obstetric unit treating a substantial volume of high-risk patients.

Our study has shown that, regardless of testing approach, antepartum assessment with FHR testing is capable of providing high specificity and high positive and negative predictive values whereas the sensitivity of either testing method is considerably lower. This is also a shortcoming of most previous reports[13] and reflects unanticipated perinatal problems, for example, abruptio placentae, intrapartum infection, prematurity, as well as the reluctance to set a cut-off point that would incorrectly classify a large number of normal fetuses. It is conceivable that ancillary assessment measures, such as multiple-parameter biophysical testing,[14, 15] could help to resolve this problem, although this remains to be convincingly demonstrated. Furthermore, biophysical testing is inherently more expensive in both equipment and personnel requirements, more time-consuming, and not available in all testing units. It is possible that further refinement of FHR testing, by the inclusion of other information such as baseline rate and variability[16] should be considered by those studying this problem in the future. Even if such improvements in antepartum testing occur, a residual group of fetuses who produce "normal" antenatal tests will have adverse perinatal outcomes, largely arising from such causes as previously mentioned. These fetuses usually elude antenatal detection as their problems occur acutely during the peripartum period. Therefore, close, continuous intrapartum fetal monitoring should be considered mandatory for all high-risk patients, regardless of the results of their antepartum FHR tests.

Discussion

DR. ALLAN G. W. MCLEOD, Miami, Florida. This is an interesting study from several standpoints. First, that anyone could get two university departments to agree to a similar protocol is a noteworthy achievement. Second, the manuscript is well written and contains a profusion of statistical data, but at times the latter seems somewhat overpowering. In fact, I went back and reread the title of the paper having questioned that I had mistakenly received a copy of a new biomedical statistics test prepared for the subspecialty Board in Maternal-Fetal Medicine. Not being a biomedical statistician I do not plan to comment further on the techniques of statistical analysis, which appeared to be thorough and detailed. As a clinician, however, I am left with a lingering reservation in my own mind as to whether the numbers involved are indeed large enough to allow us to compare perinatal death in the two groups. Third, I was impressed by the striking similarity of the perinatal problems in the two centers, although perhaps I should not have been since our own problems are comparable.

The common maternal testing protocol requiring performance of the test between 0800 and 1600 hours, 2 hours after a meal or glucose load, and without smoking for 2 hours would present major difficulties in a busy obstetric service such as ours at Jackson Memorial Hospital, where in the month of September alone we had 1206 deliveries.

Perinatal death, intrapartum fetal distress, and 5 minute Apgar scores certainly qualify as end points but I would question the decision to classify intrauterine growth retardation or postmaturity syndrome as an end point. Those would appear to be conditions that merit performance of the studies in question.

To have had only four adverse outcomes in each group reflects well on the quality of care of high-risk patients in both centers.

On reviewing the perinatal deaths in the NST group more closely, failure of the testing mechanism should not be attributed to failure of a patient to return as instructed; however, one might question the wisdom of allowing a patient to go home whose fetus showed severe intrauterine growth retardation at 35 weeks and in whom a nonreactive NST and equivocal CST had been obtained. (The "retrospectoscope" is a marvelous instrument.) It is also hard to believe that the three neonatal deaths could have been prevented.

In the nipple stimulation CST group it would appear that a positive test should not be ignored or action deferred even when it is "reactive," especially in the presence of intrauterine growth retardation. We still appear to have difficulty in interpreting the results of some tests and one certainly has to question the validity of the tests, especially the NST in the presence of a very immature fetus.

The fact that out of 1566 nonstress tests only 10 remained unsatisfactory at 60 minutes and only three were unsatisfactory at 90 minutes shows that the extended NST can have a role even in a busy unit.

The authors appear to have shown that the extended NST and nipple stimulation CST are potent weapons in our armamentarium for antepartum screening and that the decision to use one as opposed to the other should be made on the basis of specific considerations or complications of the pregnancy. The authors have outlined limitations of the techniques and have emphasized that their study is but one small step through the quicksand of antepartum fetal testing.

This article has stressed the fact that we must all recognize the importance of adequately counseling our patients to the extent that they fully understand as well as we do that a "normal" antenatal test does not guarantee that the baby is no longer at risk. They must understand that an adverse outcome can still occur, particularly during the peripartum period; hence the need for careful intrapartum monitoring in all high-risk pregnancies irrespective of the results of previous antepartum FHR tests.

The authors must be congratulated for their cooperative effort to shed a little more light in this complicated field on a prospective basis.

DISCUSSER NO. 2. I would like to make one comment that affects many of us. In private practice we are able to do NSTs easily in the office whereas the nipple stimulation test would require a hospital setting in the event of tetanic contractions.

DR. DEVOE (Closing). Dr. McLeod really has left little to respond to. I thought he was extraordinarily kind but I found The Homestead to be a very hospitable environment. I think the points that he emphasized

were the very messages we were trying to get across. One, and the one foremost, is to recognize that all testing schemes have limitations. Second, retrospectively you always criticize yourself for allowing a patient to leave the unit who perhaps should have been delivered. We all contend with difficult patients and this I think is an obstetric problem that will continue indefinitely. Finally the issue is that we should be cautious about trying to overreach the diagnostic ability of a test. Test sensitivity, which should be an ideal measure of how good a screening test is, really reflects how likely you are to predict an outcome which is going to happen sometime in the future when that future is still far from the time the test was done. The point made about where the test is performed is a crucial one. When we are doing contraction stress testing at MCG, we do it in an environment of the labor and delivery area. Tetanic contractions can occur with either testing approach and of course, with our approach, we have already selected the babies who are at the highest risk for having an abnormal CST. That makes it much more inconvenient for the practitioner whose labor and delivery setting might not be proximal to the office, although it is safer for the patient.

Ovarian prostaglandin synthase: Immunohistochemical localization in the rat

Thomas E. Curry, Jr., Ph.D., Anita Malik, B.S., and Martin R. Clark, Ph.D.
Miami, Florida

Ovarian prostaglandin synthase is stimulated by the luteinizing hormone surge resulting in the preovulatory increase in prostaglandins. In the present study, the ovarian cellular localization of prostaglandin synthase was identified by immunohistochemistry. Ovaries were collected from 27-day-old rats at the time of stimulation with pregnant mare serum gonadotropin (8 IU) (zero hours), 48 hours later, or 8 hours after administration of human chorionic gonadotropin (5 IU). At zero hours prostaglandin synthase immunostaining was present in the theca of larger follicles and interstitial regions. The number and intensity of immunostained cells in the theca increased between zero and 48 hours. The granulosa cell layer adjacent to the basement membrane in large antral follicles exhibited immunostaining. A similar staining pattern was observed 8 hours after human chorionic gonadotropin. These observations indicate that in the rat, the theca, interstitium, and granulosa contain prostaglandin synthase immunoreactivity and may contribute prostaglandins during follicular development and ovulation. (Am J Obstet Gynecol 1987;157:537-43.)

Key words: Prostaglandins, prostaglandin synthase, ovary, follicle, ovulation

Prostaglandins (PGs) act as important intercellular mediators of hormone action. In the ovary, the preovulatory increase of luteinizing hormone (LH) induces a fivefold increase in the activity of PG synthase, the enzyme that regulates the rate-limiting step in PG synthesis. The stimulation of PG synthase activity by LH results in an increase of ovarian PG levels that reach a maximum at the time of ovulation.[1] The preovulatory increase in PGs appears to be essential for follicular rupture to occur according to results of studies in which PG synthesis has been inhibited and ovulation is blocked.[1,2] The mechanisms by which PGs control this rupture, however, are uncertain. It has been proposed that PGs promote smooth muscle contractility in the follicular wall, resulting in rupture of the follicular apex already weakened by proteolytic enzymes.[1,2] PGs may also act on the vasculature to influence ovarian hyperemia.

Although the hormonally mediated control of PG production has been extensively investigated, the cellular localization of ovarian PG synthase has received little attention. The development of a monoclonal an-

tibody to PG synthase in our laboratory has provided a unique probe necessary to identify the cells containing PG synthase and to further characterize the action of LH on enzyme synthesis and activity.[3] The PG synthase antibody has been used to demonstrate a threefold increase in PG synthase protein after stimulation with human chorionic gonadotropin (HCG). These findings indicate that the HCG-stimulated increase in preovulatory PGs results in part from de novo synthesis of the enzyme, a question that previously could not be addressed with existing methodologies.[3] The purpose of the present study was to examine the ovarian cells containing PG synthase by immunohistochemical techniques. Cellular identification of PG synthase was accomplished by first optimizing the immunohistochemical staining in a known positive control tissue, kidney,[4] and subsequently identifying the cells containing PG synthase in the rat ovary.

Methods

Animals. Immature female rats (Sprague-Dawley, Charles River) were housed under controlled environmental conditions with 14 hours of light and given free access to water and rat chow. At 27 days of age, animals were primed with 8 IU of pregnant mare serum gonadotropin (PMSG) between 0900 and 1100 hours to stimulate follicular development. Fifty-two hours after administration of pregnant mare serum gonadotropin, rats were injected with 5 IU of HCG to initiate ovulation. Animals were killed and postmortem examinations performed at the time of pregnant mare serum gonadotropin priming (zero hours), 48 to 51 hours later (48 hours), or at 8 hours after HCG administration (8 hours HCG). The ovaries and kidneys were removed, cleaned of adnexa, and embedded and immunostained as described later.

Tissue preparation. Tissues were immersion-fixed as described later, dehydrated, and embedded in paraffin. The effect of different fixatives on preservation of antigenic integrity was tested by the use of 10% neutral buffered formalin, Bouin's solution, paraformaldehyde (1% to 4%), and/or glutaraldehyde (0.25% to 4%). Tissues were serially sectioned (5 μm) and PG synthase localized as described later.

PG synthase antibody. Monoclonal antibodies to PG synthase purified from sheep seminal vesicles were prepared as described previously.[3] Briefly, PG synthase was purified from sheep seminal vesicle membranes by chromatography on diethylaminoethyl cellulose and Lentil Lectin Sepharose. Balb/c mice were immunized with 50 μg of PG synthase, screened for antibody production by immunoprecipitation and enzyme immunoassay, and splenic lymphocytes fused to SP2/O myeloma cells. Hybridoma medium containing PG synthase–specific antibodies, as determined by enzyme-linked immunosorbent assay and immunoblots, was used for immunohistochemistry.

Immunohistochemistry. Immunohistochemistry was performed with the Vectastain avidin-biotin complex (ABC) peroxidase procedure (Vector Laboratories, Burlingame, Calif.) as described by Hsu et al.[5] The endogenous peroxidase activity was blocked with 0.3% hydrogen peroxide for 20 minutes. Tissue sections were rinsed with phosphate-buffered saline (10 mmol/L sodium phosphate, 4 mmol/L potassium phosphate, 0.15 mol/L sodium chloride, pH 7.4) before treatment with 1% normal swine serum for 30 minutes to reduce nonspecific background staining. Excess serum was blotted and the sections were sequentially incubated with anti-PG synthase (1:20) for 30 minutes, biotinylated rabbit antimouse IgM (1:600) for 30 minutes, and preformed ABC (1:160) for 45 minutes. After each step, the sections were washed with phosphate-buffered solution (three changes for 2 minutes each). Peroxidase activity was demonstrated by incubation in 0.05% 3,3′-diaminobenzidine containing 0.03% H_2O_2. The sections were rinsed with water, dehydrated through ascending concentrations of ethanol, immersed in xylene, and coverslipped. The slides were examined by bright field and Normarski interference light microscopy.

The immunohistochemical specificity was examined by substitution of the primary antibody with phosphate-buffered solution, normal swine serum (1:10), or a monoclonal progesterone antibody, or by omitting the secondary antibody. In addition, the primary antibody was preabsorbed with PG synthase (10 μl of antibody: 90 μl [45 μg] of antigen) for 1 hour at 22° C before being processed for immunohistochemistry.

Morphometric analysis. Quantitative evaluation of ovarian immunostaining was obtained by means of a grid overlay method as described by Weibel and Bolender.[6] Ovaries were serially sectioned at 5 μm and on every fifteenth section a grid containing 42 points was placed over follicles containing an oocyte. The percentage of points falling on a stained cell in the theca, interstitial, or granulosa cell compartments versus the total number of points counted for that cell type (stained and unstained) were tabulated. The relative immunostaining intensity of the theca, interstitium, and granulosa was scored on a 0 to 3 scale where 0 represents no staining and 3 indicates a maximum staining. Follicular diameter was determined by two measurements taken at right angles.

Statistics. An analysis of variance was used to test differences between the mean number of stained cells in the theca or granulosa in follicles of the same diameter collected at different treatments (i.e., times after pregnant mare serum gonadotropin or HCG administration) or in follicles of varying size within the same

treatment or in the interstitium at different treatments. If significance was obtained with analysis of variance, the Duncan multiple range procedure was used to test for group comparisons.[7]

Results

Effect of fixation on PG synthase immunostaining. Superior preservation of the antigen was observed in tissues fixed in 2% to 4% paraformaldehyde and 10% neutral buffered formalin. Fixation of kidney tissue in either paraformaldehyde or formalin resulted in immunostaining of the collecting tubules in the medullary regions (Fig. 1). The loops of Henle were unstained. Immunohistochemistry of kidney tissue fixed in Bouin's solution demonstrated a similar pattern of staining as observed for paraformaldehyde and formalin with the exception that a general, diffuse, connective tissue staining was present. The addition to 4% paraformaldehyde of glutaraldehyde in concentrations as low as 0.25% diminished the immunoreactivity of PG synthase staining.

In ovarian tissue, a similar paradigm for the effect of fixation on immunostaining was observed. Fixation in either 2% to 4% paraformaldehyde or formalin resulted in superior antigen preservation compared with that obtained in either Bouin's solution or parafor-

*0 hr = ovaries collected at the time of priming with PMSG. N = 5 ovaries with an average of 8 sections per ovary and 39 follicles per ovary examined. 48 hr = ovaries collected 48 to 51 hr after priming with PMSG. N = 4 ovaries with an average of 12 sections per ovary and 70 follicles per ovary counted. 8 hr HCG = ovaries collected 8 hr after administration of HCG to PMSG–primed animals. N = 3 ovaries with an average of 10 sections per ovary and 52 follicles per ovary analyzed.

†Percentage represents number of immunostained cells compared to the total number of cells counted. Values within the theca or granulosa with different superscripts are significantly different, $p < 0.05$.

‡Relative score = staining intensity graded on a 0 to 3 scale where 0 = no staining and 3 = maximum staining.

maldehyde with glutaraldehyde. All of the studies localizing ovarian PG synthase at different stages of follicular development were performed on tissues fixed with 4% paraformaldehyde.

Ovarian PG synthase localization. In ovaries collected at the time of priming with pregnant mare serum gonadotropin (zero hours; N = 7 animals, N = 5 ovaries morphometrically analyzed, 39 follicles per ovary), PG synthase was present in the theca of the follicles >100 μm diameter and in the interstitial regions (Fig. 2). The number of stained cells in the theca increased as the follicle size increased ($p < 0.01$) up to 300 μm in diameter (Table I). In the interstitial regions, 62% ± 2% of the cells exhibited intense immunoreactivity. Immunostaining was seldom observed in the granulosa cell layer regardless of follicular diameter (Table I).

A similar pattern of immunostaining was present in ovaries collected 48 hours after administration of pregnant mare serum gonadotropin (N = 7 animals, N = 4 ovaries morphometrically analyzed, 70 follicles per ovary). PG synthase was observed in the theca and the number and intensity of stained cells increased ($p < 0.01$) with increasing follicular size up to 300 μm (Table I). Intense staining was present in 72% ± 2% of the cells in the interstitial region (Fig. 3). The granulosa layer was almost absent of cells containing PG synthase in follicles less than 400 μm in diameter. In 75% of the follicles greater than 400 μm in diameter, the mural granulosa cells contained PG synthase immunoreactivity (Table I).

In ovaries collected 8 hours after administration of HCG (N = 8 animals; N = 3 ovaries analyzed morphometrically; 52 follicles per ovary), the theca, granulosa, and interstitial regions displayed PG synthase staining similar to ovaries collected 48 hours after stimulation with pregnant mare serum gonadotropin (Table I). In the interstitium 66% ± 2% of the cells exhibited intense immunostaining. Granulosa cells adjacent to the basement membrane exhibited a punctate staining pattern (Fig. 4). Ovarian sections incubated with preabsorbed antibody, with swine serum, or with a monoclonal progesterone antibody did not exhibit immunostaining (Fig. 5).

Comment

In the present study, a monoclonal antibody to PG synthase was used to identify the cellular origin of the enzyme in the rat ovary. The demonstration of ovarian PG synthase reflects the cellular content of immunoreactive enzyme and is not an index of PG production by the various ovarian compartments. The immunohistochemical localization of PG synthase was first optimized in kidney where the cellular origin of the enzyme has previously been reported.[4] Smith and Wilkin[4] observed immunofluorescence present in the collecting tubules of the kidney medulla and the interstitial cells of the renal papilla. In the present study, PG synthase

PG synthase staining *(arrows)* is present in the interstitium *(I)* and theca *(T)*. Granulosa cell layer *(G)* is unstained. *A* = antrum.

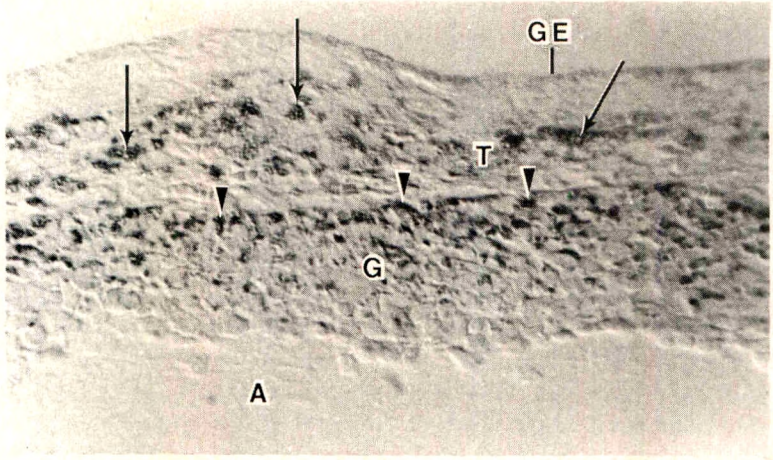

Fig. 4. Photomicrograph of a preovulatory follicle from an ovary collected 8 hours after administration of human chorionic gonadotropin and immunostained for prostaglandin synthase. Staining is present in the mural granulosa cells *(G, arrowheads)* and theca *(T, arrows)*. *A* = antrum; *GE* = germinal epithelium.

staining after fixation in paraformaldehyde exhibited a similar pattern of immunostaining in the rat kidney. Background staining of the connective tissue was observed in tissues fixed in Bouin's solution and antigenicity was destroyed by fixation in glutaraldehyde. Smith and Rollins[8] also reported superior PG synthase preservation with paraformaldehyde fixation and abolition of antigenicity with glutaraldehyde.

Although the hormonally mediated control of ovarian PG production has been studied,[1] the cells that contain PG synthase and consequently are responsible for PG production have not been positively identified. The sites of PG synthesis have been inferred by biochemical analysis of PG levels in separated ovarian compartments. In the rabbit, the granulosa cell layer has previously been reported to produce 2 to 4 times more PGF than cultured thecal tissue.[9] Triebwasser et al.[10] observed that cultured rabbit granulosa cells produced five times more PGE and nine times more PGF than the cultured residual wall of preovulatory Graafian follicles, suggesting that the granulosa is the major site of PG synthesis. In the human, both the theca and the granulosa have been reported to produce substantial amounts of PGs in culture.[11, 12] Patwardhan and Lanthier[12] found that, on a per follicle basis, the theca demonstrated a greater capacity to produce PGs in vitro

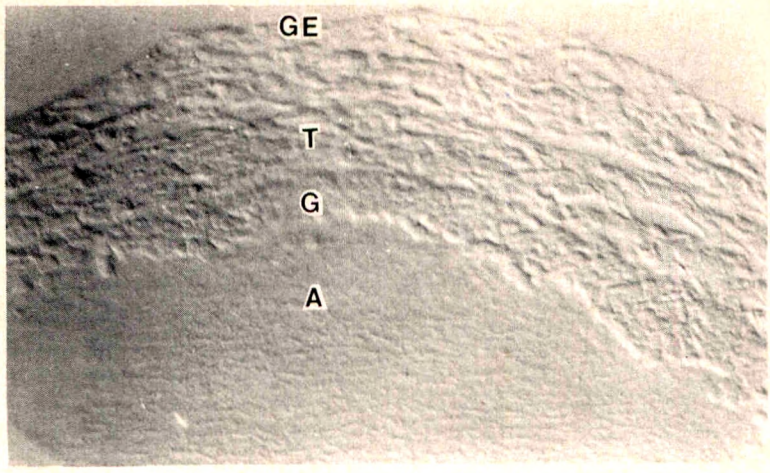

Fig. 5. Photomicrograph of a preovulatory follicle from an ovary collected 8 hours after administration of human chorionic gonadotropin and immunostained for prostaglandin (PG) synthase. The antibody was preabsorbed with PG synthase before immunostaining. Immunostaining was absent. *A* = antrum; *G* = granulosa; *GE* = germinal epithelium; *T* = theca.

than the corresponding granulosa cells. However, thecal PG production was not stimulated by gonadotropins.

Isolated rat granulosa cells respond to an LH stimulation with a significant increase in PG production[1] and this ovarian compartment has been proposed as the predominant source of PG synthase in the rat. In contrast to these findings, Lindner et al.[2] observed that, in follicles isolated from proestrus rats, the follicle wall produced approximately fourfold more PGE than an equivalent number of granulosa cells. The observations from the present study, which quantitate immunoreactivity instead of enzyme activity, support the role of the theca and surrounding interstitial cells in the production of ovarian PGs. PG synthase was present in the theca of larger antral follicles in ovaries collected from animals before exogenous hormonal stimulation. Of particular interest was the increase in number and intensity of immunostained cells in the theca after administration of pregnant mare serum gonadotropin, indicating a hormonal regulation of thecal PG synthase. Thecal PGs may modulate early follicular development since PGE_2 can mimic the action of follicle-stimulating hormone (FSH) on granulosa cells and of LH on thecal cells.[11] PGE produced by the theca may diffuse across the basement membrane and assist in the induction of FSH receptors and FSH responsiveness of granulosa cells in immature follicles. In addition, PGs may act in an LH-like manner on the theca of adjacent follicles assisting in follicular growth.[11] Thus the theca may be an important source of PGs during follicular development in the rat.

The granulosa cells contained PG synthase only in large preovulatory follicles. It is well documented that follicular PGs increase 3 to 5 hours after an LH stimulation.[1, 2] The lag period has been postulated as a period of de novo synthesis of the enzyme. Our observation of PG synthase present in the granulosa cells before HCG administration may represent either the natural sequence of differentiation and maturation of the granulosa cell layer after an FSH-like stimulation, a partial response to exogenous LH present in the pregnant mare serum gonadotropin, or stimulation by endogenous LH. The presence of PG synthase staining in 9 of 12 preovulatory follicles suggests that this is not a spurious observation but may reflect endogenous or exogenous LH action present in the pregnant mare serum gonadotropin–stimulated peripubertal animal. In future studies, PG synthase will be localized during the estrous cycle of adult rats. This paradigm will allow examination of granulosa cell staining before and after the endogenous LH surge in the absence of possible exogenous LH action from treatment with pregnant mare serum gonadotropin.

PG synthase staining in granulosa cells was present in a heterogenous distribution. Immunostaining was distributed only in granulosa cells adjacent to the basement membrane. The mural granulosa cells exhibited a punctate staining pattern, which was markedly different than the pattern observed in the theca and interstitial cells. Our observations are consistent with the concept of a heterogenous granulosa cell population as proposed by other workers examining hormonal stimulation of granulosa cells,[13] cytochrome P-450 activity,[14] and cell surface antigens.[15] For example, Goldring et al.[14] noted a regional variation in cytochrome P-450 activity such that granulosa cells adjacent to the basement membrane had an increase in FSH-stimulated

cytochrome P-450 activity compared with cells located in deeper layers. In addition, FSH initiates differentiation of a surface membrane antigen in only the mural granulosa cells.[15]

In summary, the present results demonstrate for the first time that, with immunohistochemistry, the theca and interstitium of the rat ovary contain PG synthase. The change in thecal immunostaining may reflect follicular differentiation caused by stimulation with pregnant mare serum gonadotropin. The mural granulosa cells of large preovulatory follicles also exhibited an increased quantity of PG synthase. In the rat, the theca, interstitium, and granulosa all appear to contribute to ovarian PGs.

The didactic criticisms of Dr. William LeMaire throughout all stages of this project are gratefully acknowledged. The assistance of Drs. Mehrdad Nadji and Jocelyne Weissman of the Department of Pathology and the technical help of Brad Ress were fundamental during the early stages of immunohistochemical optimization. We appreciate the provision of pregnant mare serum gonadotropin by the National Hormone and Pituitary Program, National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases.

Evaluation of the atypical Pap smear

D. E. Darnell Jones, M.D., William T. Creasman, M.D., Raymond A. Dombroski, M.D., Samuel S. Lentz, M.D., and John L. Waeltz, M.D.

Greenville and Durham, North Carolina

Two hundred thirty-six consecutively referred patients with "atypical" but not dysplastic Pap smears were evaluated by colposcopy and directed biopsies to assess the significance of this ambiguous result. Additionally the histologic diagnosis was compared with the results obtained by repetition of the Pap smear, interpretation of cervigrams, and the visual impression of the colposcopist to evaluate the accuracy of these three modalities as intermediate screening procedures. Fifty-eight patients (25%) had biopsy-proved cervical intraepithelial neoplasia. Repeat Pap smears identified only 17% of these patients. Colposcopists noted atypical transformation zones in 97% of the patients with cervical intraepithelial neoplasia. Cervigrams identified 81% of the cervical intraepithelial neoplastic lesions but had a 15% method failure (uninterpretable). The time-honored tradition of repeating atypical smears before definitive diagnostic procedures are performed is to be condemned. Neither colposcopy nor cervicography was judged to be an ideal intermediate screening procedure, but both were superior to Pap smear repetition. (Am J Obstet Gynecol 1987;157:544-9.)

Key words: Cervical intraepithelial neoplasia, Pap smear, colposcopy, cervicography

Screening Pap smears that are compatible with cervical intraepithelial neoplasia dictate further patient evaluation and establishment of a histologic diagnosis. Patients with cytologically normal screening Pap smears require only continued periodic screening. Other screening smears are variously reported as containing "atypical" cells. Most frequently these cytologic abnormalities can be attributed to recognized inflammatory conditions. Of more concern are those smears that have a significant but nondiagnostic abnormality that cannot be immediately attributed solely to inflammation. Early neoplastic lesions may have minimal cytologic abnormalities. Samples from more advanced lesions may contain only a small number of atypical cells and not be representative of the entire lesion. In other instances the reported atypia may represent diagnostic uncertainty. The next appropriate step in the management of these patients remains unclear.

A critical correlation of these smears with subsequent histologic findings may permit the clinician to assess the significance of these ambiguous smears provided that there is consistency in the evaluation of the cytologic changes and accuracy in the establishment of a histologic diagnosis. Preliminary unreported data in the colposcopy clinic at East Carolina University suggested that nondysplastic screening pap smears interpreted as "class II significant cellular atypia" by the state cytology laboratory were associated with histologic cervical intraepithelial neoplasia and invasive carcinoma in a sufficient number of patients to warrant further evaluation of these patients. Recent studies in other institutions have shown that a significant number of patients with atypical cytologic findings when evaluated are found to have cervical intraepithelial neoplasia.[1, 2]

Because of an increasing number of these patients being seen in our clinic, we additionally evaluated cervicography, simple repetition of the Pap smear, and colposcopy without biopsy as potential intermediate screening methods in these patients.

Material and methods

Two hundred thirty-six consecutively referred nonpregnant patients with class II significant cellular atypia Pap smears were evaluated. Repeat Pap smears were obtained from the endocervix and portio with wooden spatula and a saline-moistened cotton swab. Cervigrams, 35 mm color slides, were made of the transformation zone in the manner described by Stafl.[3] Colposcopy was then performed by one of three faculty members proficient in colposcopy, and directed biopsy specimens of the cervix were obtained. The transformation zone was biopsied in all patients and the histologic diagnosis was established as the reference point for evaluation of the proposed intermediate screening procedures. Endocervical curettage was performed if anything other than native columnar epithelium was present in the endocervical canal.

Pap smears and biopsy specimens were interpreted

From the Departments of Obstetrics and Gynecology, East Carolina University and Duke University.

independently. Cervigrams were interpreted without knowledge of cytologic or histologic findings by an experienced colposcopist and reviewer of cervigrams who was not otherwise involved in patient evaluation or care.

Cytologic and histologic findings were reported as benign, cervical intraepithelial neoplasia I, cervical intraepithelial neoplasia II, or cervical intraepithelial neoplasia III. Colposcopists were required to identify and report as suspicious transformation zones containing aceto-white epithelium with or without the vascular changes of punctation and mosaicism that, in their estimation, potentially represented cervical intraepithelial neoplasia and warranted biopsy. If the entire transformation zone was not visible, the colposcopy was considered and reported as unsatisfactory.

Cervigrams were interpreted as: (1) transformation zone entirely seen and normal, (2) transformation zone not entirely seen but no abnormalities seen, (3) no transformation zone seen—unsatisfactory, (4) technically defective (inadequate visualization of the cervix), or (5) if aceto-white epithelium with or without associated vascular changes thought to be compatible with cervical intraepithelial neoplasia was visible, the cervigram was considered and reported as suspicious.

If the initial Pap smears obtained in our clinic suggested cervical intraepithelial neoplasia I but the histologic findings we obtained at that initial visit failed to identify cervical intraepithelial neoplasia, the patient was reevaluated by colposcopy, additional biopsies, and Pap smear. If these additional biopsy specimens failed to demonstrate cervical intraepithelial neoplasia and the second Pap smear was benign, the benign histologic diagnosis was accepted. If the initial Pap smear obtained in our clinic suggested cervical intraepithelial neoplasia II or III that could not be confirmed by the colposcopic-directed biopsies obtained at that visit, the patient was similarly reevaluated. If cervical intraepithelial neoplasia could not be confirmed by histologic examination of the additional biopsy specimens in these patients, a conization was performed.

The correlation between the results of each of the proposed intermediate screening procedures and the final histologic diagnosis was made according to the following definitions: sensitivity = true positive/true positive + false negative; specificity = true negative/true negative + false positive; positive predictive value = true positive/true positive + false positive; and negative predictive value = true negative/true negative + false negative.

Results

The mean interval between screening Pap smears and the initial evaluation visit was 4.7 months (range 3 to 52 weeks) and the mean age of the patients was 25 years (range 13 to 63 years). Fifty-eight of the 236 patients (25%) had histologically proved cervical intraepithelial neoplasia. No patients had invasive carcinoma. The correlation between the cytologic findings obtained in our clinic and the histologic diagnosis is displayed in Table I. These Pap smears identified only 10 of the 58 patients (17%) with cervical intraepithelial neoplasia. Only five of the 10 patients with cervical intraepithelial neoplasia II or III were identified by cytologic tests. Four patients whose initial Pap smears in our clinic suggested cervical intraepithelial neoplasia I or II could not be proved by initial histologic findings to have cervical intraepithelial neoplasia. Further evaluations did not identify histologic cervical intraepithelial neoplasia in any of these patients.

The correlation between the cervigram interpretation and the histologic diagnosis is shown in Table II. Cervicography was unsatisfactory in 13 (6%) and technically defective in 22 (9%) of the 236 patients. Excluding these 35 patients, 52 of the remaining 201 patients had cervical intraepithelial neoplastic histologic findings. Forty-seven (90%) of these patients were identified by cervicography. None of the nine patients with cervical intraepithelial neoplasia II or III who had interpretable cervigrams had a negative cervigram result.

The correlation between the visual interpretation of the colposcopist and the histologic finding is shown in Table III. Fifty-six of the 58 patients (97%) with cervical intraepithelial neoplasia were considered to have suspicious colposcopic examinations. Colposcopy was judged to be unsatisfactory in two patients with endocervical cervical intraepithelial neoplasia.

Suspicious	128	46	7	3	184
Unsatisfactory	0	2	0	0	2
Total	178	48	7	3	236

CIN, cervical intraepithelial neoplasia.

The correlation between the interpretation of the colposcopist and the interpretation of the cervigram is shown in Table IV. The frequency with which cervical intraepithelial neoplasia was found is shown for each of the possible pairings. Five patients with biopsy-proved cervical intraepithelial neoplasia had cervigrams that were judged to be negative but the transformation zone was not entirely seen. Colposcopists identified three of these five as suspicious. All cervical intraepithelial neoplastic II and III lesions were identified by both techniques provided that the study was satisfactory.

The correlation between the final histologic diagnosis and the result of each of the proposed intermediate screening procedures is shown in Table V. A normal repeat Pap smear was frequently falsely reassuring and a positive repeat smear added no new information. Routine repetition of Pap smears at local health departments significantly delayed referral and definitive diagnostic procedures in this study. Both colposcopy and cervicography were sufficantly sensitive to be considered as potential intermediate screening procedures. In this study cervicography had greater specificity and a higher positive predictive value than did colposcopy.

Comment

There appears to be an increasing number of patients with atypical smears. The proper management has not been defined. In many instances this is a "wastepaper basket" term and the cytologist must describe in detail the interpretation of this entity. Unfortunately, the definition may vary from laboratory to laboratory. Evaluating all patients with atypical smears by colposcopy and directed biopsies exceeds the ability of referral centers to provide this service in many areas. Because 25% of these patients in our study had cervical intraepithelial neoplasia, we feel that further evaluation of patients with atypical smears should be carried out. If an ideal intermediate screening procedure could be identified, the unnecessary use of limited colposcopic services could be avoided without an accompanying compromise of patient care.

In our experience, a repeat Pap smear did not help to identify the patient with cervical intraepithelial neoplasia. The repeat Pap smear most frequently was benign. Only 17% of the patients with cervical intraepithelial neoplasia were identified by the repeat cytologic testing. This prompted a review of both cytologic and histologic material. It became apparent that there was significant variation between pathologists within a single institution and between pathologists in different institutions in the interpretation of mildly atypical histologic changes in the epithelium. Similar variations occurred when cytologic interpretations were subjected to similar internal and external review. It appears that it is extremely difficult to differentiate between reactive changes in immature squamous metaplasia and very early neoplastic changes. With these findings we cannot advocate simple Pap smear repetition as the sole method of evaluation of these patients and the time-honored practice of repeating atypical smears should be abandoned. Other authors have noted a significant

false negative rate in repeat Pap smears and have advised against repeating smears to confirm cytologic abnormalities.[4-6]

Colposcopists identified all patients with exocervical cervical intraepithelial neoplasia and the two patients with isolated endocervical cervical intraepithelial neoplasia were considered to have had unsatisfactory examinations. Unfortunately colposcopy did not, in this study, reduce the demand on clinical services because most patients were felt, on the basis of visual inspection, to require biopsy. Two patients with unsatisfactory colposcopic examinations represent a 1% method failure.

Cervicography has limitations when compared with colposcopy. The absence of an exocervical transformation zone resulted in unsatisfactory studies in 6% of the patients. This is probably an irreducible number in this study population. Unsatisfactory studies occurred more frequently, but not exclusively, in elderly patients. Nine percent of the studies resulted in technically defective cervigrams. Because experience was gained during the course of the study, the frequency of technically defective cervigrams decreased. It is important to take as much care to prepare the cervix for cervicography as is done for colposcopy. The combination of unsatisfactory and technically defective studies resulted in a 15% method failure rate. Manipulation of the cervix to expose the endocervical canal and the ability to continuously focus the colposcope makes the method failure rate extremely low with colposcopy. Five patients with biopsy-proved cervical intraepithelial neoplasia I had normal cervigrams. No patients with cervical intraepithelial neoplasia II or III had normal cervigrams. Our experience with cervicography in this setting suggests that this alternative way of screening for abnormalities of the epithelium in the transformation zone is superior to simple Pap smear repetition. If the intent of intermediate screening is to identify only significant lesions, cervicography may permit more efficient use of limited resources. The cervix can be photographed at a remote site and the cervigram reviewed by a competent colposcopist without transportation of the patient to the referral center. This study suggests that advanced cervical intraepithelial neoplastic lesions can be identified by this technology.

In our opinion, the limitations of cervicography make it an unacceptable substitute for colposcopy when the intent is to establish a diagnosis. Cervigrams do provide good photographic documentation of the exocervical transformation zone. Because a small number of patients with cervical intraepithelial neoplasia I were not identified by cervicography, the decision to use this as a intermediate screen in the patient with an atypical Pap smear should be based on local constraints in the health care system. Colposcopy and directed biopsies are the standard by which this technology should be judged. If cervicography is used as an intermediate screen, it should be with the clear knowledge that all patients with unsatisfactory study results must be evaluated further, that technically defective studies must be repeated, and that patients with normal cervigrams should not be considered disease free on the basis of cervicography alone.

Discussion

Dr. George L. Mayer, Jacksonville, Florida (Official Guest). Dr. Jones and his colleagues have performed a detailed analysis of different courses of evaluation for the class II "atypical, but not dysplastic" Pap smear. They concurrently evaluated, by several methods, 236 consecutive referrals from their North Carolina state cytology laboratory. The goal was to avoid the necessity for definitive colposcopy. The standard for accuracy was pegged to colposcopy with directed biopsy, endocervical curettage, and conization when indicated. The intermediate screening techniques evaluated were: (1) repeat Pap smear, (2) cervicography, and (3) screening colposcopy without biopsy.

Of the 236 patients, 58 were demonstrated to have cervical intraepithelial neoplasia, but only 10 of the 58 (or 17%) had a second Pap smear that was still atypical or had become dysplastic. This was despite a mean interval of 4.7 months between Pap smears. Repeat smears did not detect 43 cervical intraepithelial neoplasia I lesions, four cervical intraepithelial neoplasia II lesions, and one cervical intraepithelial neoplasia III lesion.

These data strongly suggest that Pap smears from the North Carolina state laboratory that are reported as "class II, atypical, but not dysplastic" are obtained from patients whose histologic findings are likely to demonstrate dysplasia 25% of the time. This is clearly a distressing problem. Dr. Jones has indicated, in a personal correspondence, that the laboratory reports 55,000 such Pap smears each year for North Carolina.

If the statistics presented in the article can be extrapolated to encompass the entire 55,000 Pap smears, approximately 11,000 patients could have dysplasias missed by a second Pap smear. How many of these lesions would subsequently be detected by additional smears or would progress to outright cancer is, of course, uncertain.

Some indication of the risks for progression can be estimated by referring to studies that have addressed this problem. One such study by Hall and Walton[1] was published in 1968. In that study 206 patients with histologically proved dysplasias, mostly mild, were followed for up to 14 years. Almost 20% of mild dysplasias progressed to more severe lesions, with 6.2% reaching the level of carcinoma in situ. For more advanced dysplasias the progression rate was much higher. Moderate dysplasias became carcinoma in situ in 12.9%, and severe dysplasias became carcinoma in situ in 29.1% of cases. This was before the practice of combining severe dysplasias and carcinoma in situ into cervical intraepithelial neoplasia III.

In 1964 Stern and Neely[2] concluded that patients with dysplasias have a risk of developing carcinoma in situ more than 1000 times greater than have women without documented dysplasia. The risk for developing invasive cancer of the cervix is 100 times greater than for women without documented dysplasia.

Another concern with missed dysplasias is that the transit times from early to advanced lesions may be faster than many realize. Richart and Barron[3] have estimated from a series of their studies that the mean transit time from mild dysplasia to carcinoma in situ is only 5.8 years, and that from more advanced dysplasias is much faster.

A prevailing practice has been to treat the patient for cervicitis and to perform several Pap smears at relatively frequent intervals after reports of atypia without dysplasia. This is on the basis that with each Pap smear dysplasias become less likely to escape detection. This introduces the uncertainty of patient compliance, making it very important to "know your patient."

A confusing factor has been that the reporting of Pap smears varies from laboratory to laboratory and from pathologist to pathologist. Many gynecologists have learned from experience that a class II Pap smear from one laboratory may be labeled class III in another. The old adage of "know your lab" becomes very important when deciding one's course of evaluation for Pap smears with low-level abnormalities.

Current trends in private practice are making "know your patient" and "know your lab" less obtainable goals. Health maintenance organizations and preferred provider organizations assign and reassign patients as affiliations change. Contractural agreements between third-party payers and laboratories shift regularly in my community. These trends reinforce my agreement with Dr. Jones when he condemns "routine repapping" of "abnormal, but not dysplastic" Pap smears or of Pap smears reported by other laboratories that suggest the same thing.

With regard to the cervicography component of his study, Dr. Jones reports 15% of cervigrams to have been unsatisfactory or technically defective. This compares very favorably with Blythe's report,[4] published in 1985, in which 53.9% of cervigrams were unsatisfactory or technically defective. Stafl,[5] who is the prime proponent of cervicography, reported 19.7% defective or unsatisfactory cervigrams in his 1981 report.

I am curious about the qualifications of the personnel who obtained the cervigrams in the study by Jones et al. If resident physicians obtained the cervigrams, this might explain their success. Jones et al's. rate of defective or unsatisfactory cervigrams would probably be less obtainable if performed in outlying areas for later review by colposcopists. Probably results would more closely parallel Blythe's experience,[4] unless there

was intensive training of those individuals who will obtain the cervigrams. I also suspect that some additional training of colposcopists would be required to make them comfortable interpreting the cervigrams.

Colposcopy has become much more readily available, and most gynecologists perform it regularly. Cervicography is not a technique that is widely available. Efforts to train individuals to perform and interpret results might be better directed to training additional colposcopists. Cervicography is not performed in my community (Jacksonville, Florida) and I have no personal experience with it. I will be very interested to see how this technique evolves over the next several years.

In his comments on screening colposcopy, Jones et al. demonstrated little decreased demand on clinical services. His findings confirmed what most colposcopists experience: "you can almost always find something to biopsy."

In conclusion, the dilemma of atypical, but not dysplastic, Pap smears persists. This study effectively demonstrates that there is not a satisfactory intermediate screening procedure to cut down on the use of colposcopy. Certainly repeat normal Pap smears should not be relied on.

Dr. Paul B. Underwood, Charlottesville, Virginia. I have two questions. One, Jones et al. mentioned that their patients were up to age 63 years. Knowing that postmenopausal women are notoriously difficult to evaluate colposcopically, did they look at their figures eliminating postmenopausal women? Second, I am concerned about their recommendations that repeat Pap smears are poor methods of evaluating a class II smear when they sent their Pap smears to a state laboratory and I would like to know if they know anything about the laboratory. It is the same cytologist who is reading it? Are they board-certified? I really feel that that is a strong recommendation to make when it is not being sent to a single cytologist and one does not know who is reading the smear.

Unknown Speaker. I would like to ask Jones et al. how they identified the patient after they had taken the picture. I did not see a marker on the picture.

Unknown Speaker. I would like to ask Jones et al. whether they distinguished between dysplasia and colpocytologic changes caused by human papilloma virus. If this distinction was not made it is likely that they found a high number of abnormalities associated with normal Pap tests.

Dr. W. Siegfried Smith, Jr., Greensboro, North Carolina. I would like to ask Jones et al. if they performed a conization after a couple of negative colposcopies. What were the figures for false positive and false negative results?

Dr. Jones (Closing). The survey and 35 mm pictures were done predominantly by one of the faculty. It is even easier than working a 35 mm camera. Most physicians who do this have a nurse who takes the pictures.

What would happen if we eliminated the postmenopausal patients? It would make the surveys look much better. Quite frankly, most of the cases in which the transformation zone could not be seen were in postmenopausal patients. We have the same problem you do when the exocervix is entirely normal in the postmenopausal woman. It is not a technology that is applicable to everybody. I do not have any figures as to what happens if we remove the postmenopausal women; we took all patients as they came.

There may be some confusion as to who does Pap smears. All the initial Pap smears were done in local health departments and the patients were referred to us. Once the Pap smears arrived at our institution they were reviewed and read by the Department of Pathology at East Carolina University and specifically screened by three cytotechnologists and reviewed by two pathologists. We know who they are and we have a fair degree of confidence in the Pap smears that we obtained in our clinics.

How did we identify the patients? The numbers are small but on the bottom right-hand corner of the cervigrams there are patient identifier numbers, so there is no way of getting them confused.

We fought the game of what is dysplasia and what is condyloma before we started this study and, yes, if you include patients with koilocytotic atypia or condylomatous atypia and start calling them dysplasia your numbers go all off the wall. I think we have some fairly rigid definitions of what represents a viral alteration of the epithelium and what represents dysplasia. I feel a fair degree of confidence when I talk about dysplasia.

Those patients who had unsatisfactory colposcopy underwent conization. There were two such patients who underwent cold-knife conization; if we had an initial Pap smear discrepancy we simply went back and redid the colposcopy and in most instances that permitted us to resolve that discrepancy. We performed conizations on all patients who had cervical intraepithelial neoplasia II or cervical intraepithelial neoplasia III Pap smears in whom we could find no lesion. We did not perform conizations on those patients who repetatively could be found to have no histologic abnormalities if they had single cervical intraepithelial neoplasia I Pap smear that we just could never prove by aggressive trials.

Regional program for prevention of premature birth in northwestern North Carolina

Paul J. Meis, M.D., J. M. Ernest, M.D., Mary Lou Moore, R.N.C., Ph.D., Robert Michielutte, Ph.D., Penny C. Sharp, M.Ed., and Paul A. Buescher, Ph.D.

Winston-Salem and Raleigh, North Carolina

We present our experience with introducing and implementing a prematurity prevention program in a 20-county region in northwest North Carolina. The program is based on the risk assessment and educational model. In the first 25 months of results available, 17,370 births occurred in women enrolled in the project. During 1985, 42.5% of all births in the region occurred in the project. During the time span examined, a downward trend was seen for rates of low birth weight births in public and private patients and for very low birth weight births in private patients. During 1985, private births in the project were significantly less likely to be low birth weight or very low birth weight than private births to women not in the project. These results suggest that regional implementation of prematurity prevention programs is feasible and that such programs are particularly appropriate for private patients. (Am J Obstet Gynecol 1987;157:550-6.)

Key words: Premature birth prevention, regional perinatal care

Most southern states, including North Carolina, experience high rates of infant mortality.[1] The majority of these large numbers of infant deaths are due to premature or low birth weight (LBW) births. Although some progress has been made in reducing the rate of infant mortality in recent years in North Carolina, little reduction has occurred in the rates of LBW births,[2] as shown in Table I. Significant further reduction in infant deaths will be achievable only by reducing the number of LBW births.

Although general agreement exists about the need for reducing the rate of LBW births, there is not a clear consensus on the means to effect this reduction or with respect to the value of current prevention strategies. The utility of a program of risk assessment, patient and provider education, and life-style modification for patients at risk has been described by Papiernik et al.[3] and found to be effective by some authors[4] and ineffective by others.[5] The potential value of this approach suggests it merits further testing.

According to the general principles set forth by Papiernik et al., a prematurity prevention project in northwest North Carolina was initiated to determine: (1) if these prevention methods could be implemented on a regional basis involving a heterogeneous population of physicians, nurses, and pregnant women in a southern state and (2) if these methods could be shown to reduce the rate of LBW births in the population of patients compared over time or compared with the LBW rates of contemporary patients not involved in the project.

Description of the program

The geographic site of the program, Perinatal Region 2, is a 20-county region in northwest North Carolina with a population of about 1,650,000 and approximately 20,000 births per year.

In meetings with physicians, nurses, county health directors, and others throughout this region, the program was explained and offered to health care providers. All of the county health department clinics and many private obstetricians and family physicians chose to use the program. Other physicians chose not to participate and pregnancy outcomes of their patients can be compared with those of patients involved in the program.

The elements of the program include: (1) risk assessment of all patients at the initial prenatal visit and again at 24 to 28 weeks, evaluated by means of a risk assessment tool derived from the work of previous investigators[6, 7]; (2) education for all patients about the signs and symptoms of premature labor and what to do if these occur; (3) education of all personnel in the health department clinic or private office concerning the importance of prompt evaluation of patients who

may be in premature labor; (4) intensive prenatal care for patients at risk for preterm births with weekly visits and cervical examinations after 24 weeks' gestation; (5) assessment of uterine activity of all patients with symptoms or signs of premature labor including appropriate use of tocolytic agents.

The program was explained, organized, and initiated in each clinic or private office by a personal visit of a nurse-educator employed by the program.

Methods

In evaluating the results of this program, all births of 501 to 2500 gm were classified as LBW and a subset of these births, 501 to 1500 gm, were defined as very low birth weight (VLBW). Births of <501 gm were not included as these births are variably reported as either live births or as spontaneous abortions.

Preliminary evaluation of the effectiveness of the project in reducing LBW births has been conducted by means of two methods. Rates of LBW and VLBW births occurring in women enrolled in the project are examined as trends from the first month of large numbers of births recorded, July 1984, to the most recent month of available data, July 1986. These data are examined by provider class: public patients from county health department prenatal clinics and private patients from private practitioners.

Second, data obtained from birth certificates for all

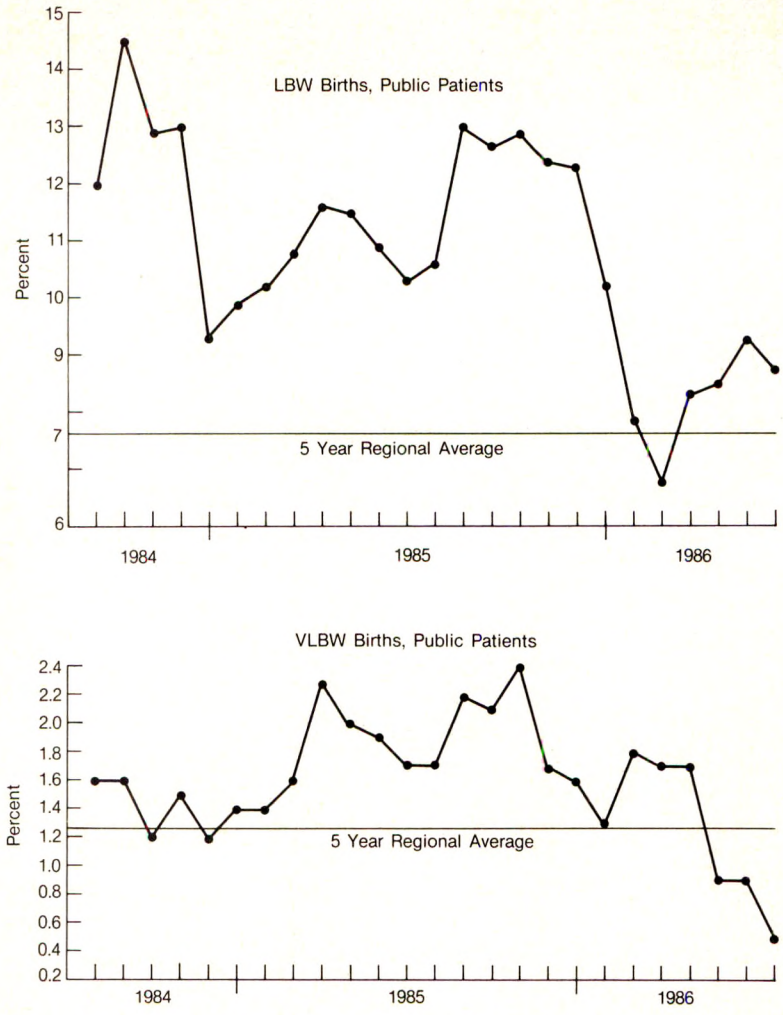

Fig. 2. Rates of LBW and VLBW births to women in the project receiving care through health department clinics.

births occurring in Region 2 in 1985 were used to compare the results of births to women in the project with births to women out of the project for 1985. Comparisons in rates of LBW and VLBW birth were made with the use of χ^2 analysis with the criterion for statistical significance at ≤ 0.05.

Results

During the time span examined, 17,370 births occurred in women enrolled in the project. For the calendar year 1985, 42.5% of all births in the region were in the project. The rates of LBW and VLBW births that occurred are shown in Fig. 1 and expressed as 3-month moving averages in order to smooth month-to-month variability. Included in Figs. 1 through 3 are historical rates of LBW (7.48%) and VLBW (1.23%) births for Region 2 for the 5 years 1980 to 1984. A downward trend is seen for rates of LBW and VLBW births, with recent cohorts of LBW and VLBW birth rates well below historical rates for the region.

Fig. 2 shows similar data for public births, which totaled 5123 (29.5% of total births in the project). Greater fluctuation is seen in rates of LBW and VLBW births, which can be explained in part by the smaller number of births in each cohort. Although rates of LBW and VLBW births are high, a downward trend is seen in the rate of LBW births, and recent cohorts show a marked improvement in rates of VLBW birth.

Fig. 3 shows results of births in private patients, whose 12,247 births constituted 70.5% of total births in the project. A downward trend is seen in rates of LBW births, and rates of VLBW births are particularly low for the last 12 months of births.

Comparisons of rates of LBW and VLBW births of private patients enrolled in the project with private patients not enrolled in the project are shown in Table II and Fig. 4. Patients receiving care through county health department clinics and patients who received no prenatal care were excluded from these data. Since all of the public health departments were participating in

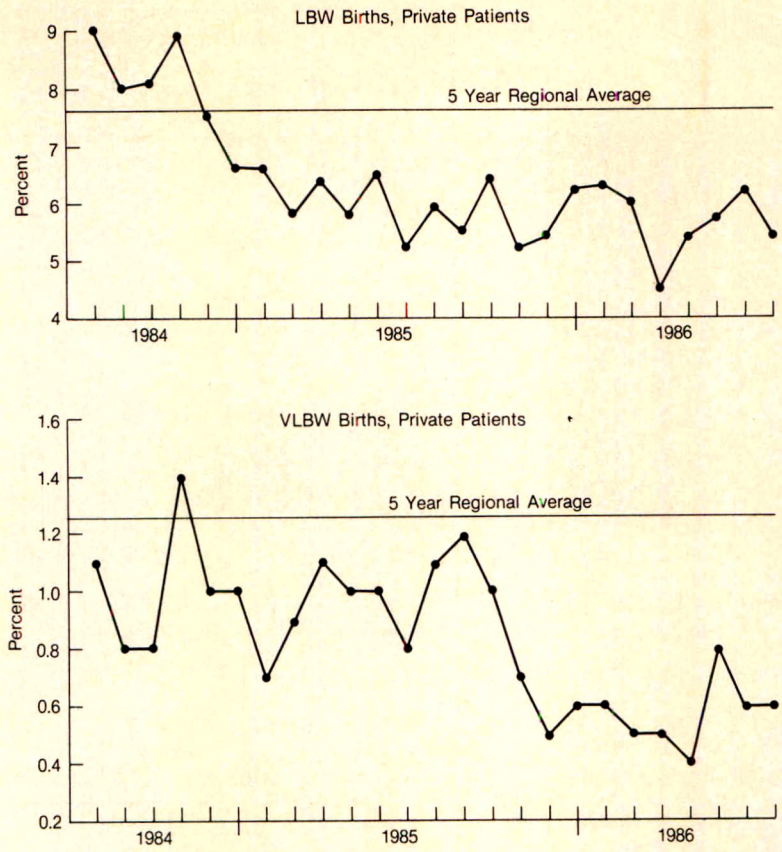

Fig. 3. Rates of LBW and VLBW births to women in the project receiving care from private physicians.

Table II. Births in private patients who received prenatal care in northwest North Carolina in 1985

	Not in project		*In project*			
	n	%	*n*	%	χ^2	*p*
Total	11,850		6,477			
501-1500 gm	151	1.27	57	0.88	5.80	0.012
501-2500 gm	870	7.34	380	5.87	14.33	0.0001

the project, a comparison of public patients in and out of the project is not possible. Rates of LBW and VLBW births were significantly lower in private patients enrolled in the project compared, by means of χ^2 analysis, with private patients not enrolled in the project. The demographic characteristics of private patients in and out of the project were examined with the use of information obtained from birth certificate data through the State Center for Health Statistics. It was possible to match 88% of 1985 births in the project with birth certificates. Some demographic characteristics are shown in Table III. The group of patients not in the project had slightly higher rates of some high-risk parameters. A more detailed description of the demographic characteristics and relationship to outcome measurements is considered elsewhere (Buescher PA, Meis PJ, Ernest JM, et al. A comparison of women in and out of a prematurity prevention project in a North Carolina perinatal care region. Submitted for publication).

Cost savings. The direct and indirect financial costs of VLBW birth (<1500 gm) are considerable. In the intensive care nursery at our hospital, hospital and physician bills for the care of these infants average $29,900. Costs in other areas of the United States are much higher. Approximately 15% of these infants will be expected to suffer from cerebral palsy. The average additional expense of raising a child with cerebral palsy to age 18 is $95,083.[9] Thus, as shown in Table IV, the average direct financial cost of each VLBW birth in northwest North Carolina is $44,162.

If the 8952 parturients enrolled in the program in

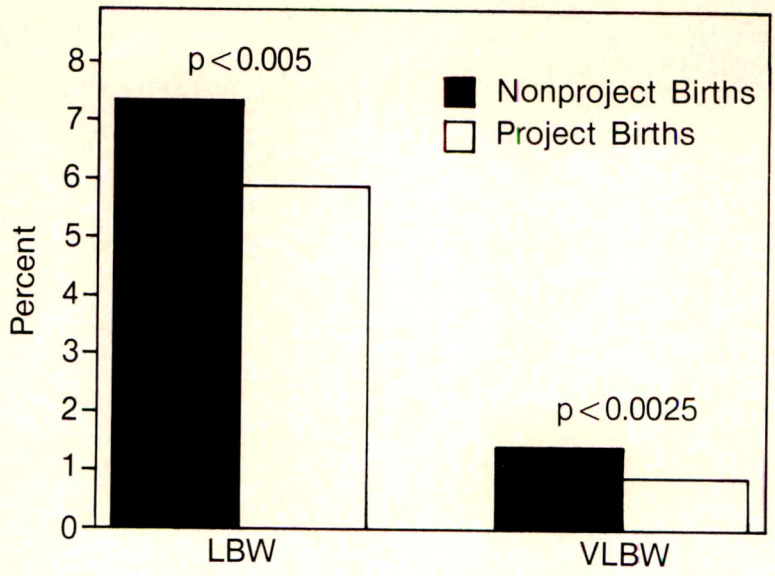

Fig. 4. Comparison of rates of LBW and VLBW births to women cared for by private physicians using the project with those to women cared for by physicians not using the project.

Table III. Demographic characteristics of private births in northwest North Carolina in 1985

	Not in project (%)	*In project (%)*
Nonwhite	19.1	14.6
Unmarried	17.2	12.2
Under age 18	5.4	4.5
Education <12 yr	23.0	20.0
Previous fetal or live-born death	16.7	17.6
Complications of pregnancy	13.0	12.8
Medicaid	8.1	5.0
WIC Program	12.7	9.5

Table IV. Average medical expenses of VLBW infants

Cost of raising child with cerebral palsy	$95,083.00
Occurrence rate of cerebral palsy	× 15%
	= $14,262.45
Mean neonatal intensive care unit expense	+29,900.00
Direct expense of <1500 gm birth	= $44,162.45

the most recent 12-month period had experienced VLBW birth at the average rate for all women in Region 2 (1.31% for 1985), an additional 23 VLBW infants would have been delivered.

This reduction in VLBW births represents a cost savings of 23 × $44,162 or $1,015,736. The direct costs of supporting the prematurity prevention program during this time period was $90,123, which represents a cost savings of $11.27 for each dollar spent on the program.

Comment

This examination of the first 2 years of births in a prematurity prevention program shows promising overall trends in reductions of LBW and VLBW births in a group of 17,370 births. Rates of LBW and VLBW births for the first calendar year of the project, 1985, also are lower than those in a contemporary group of private patients not participating in the program.

The design of this study, emphasizing widespread use throughout a region, does not permit a truly controlled study. In order to evaluate the effectiveness of such a program, an extended time span may be required to show continued improvement in rates of LBW and VLBW births. Papiernik et al.,[3] in their pioneer work in prematurity prevention, required 4 years before demonstrating effective results. Cole[10] has described the problems of maintaining effective prematurity prevention programs in the United States, where funding for programs is often for short time periods and results are expected to be demonstrated in 3 years or less.

Reductions in LBW births are most striking among private patients and among VLBW births. This observation is consistent with our previous findings that a greater percentage of LBW births in private patients is

related to idiopathic premature labor, rather than medical problems, premature rupture of the membranes, or impaired fetal growth.[11] Similarly, VLBW births were more often related to idiopathic premature labor than LBW births. Thus the apparent success or lack of success of prematurity prevention programs is likely to be affected strongly by the characteristics of the patients included in the program. Prematurity prevention projects of the type described here that focus solely on urban, inner city populations may have less chance for demonstrating success than those that are directed to other patient populations.

The data suggest that this project may be most successful in reducing the rates of VLBW infants. It is important to emphasize that since these births make up only 1% to 2% of all births, a large cohort of births must be examined to identify a significant reduction. Several previous studies have had relatively small cohorts of parturients, making examination of reductions in rates of the VLBW category difficult.[4, 5] Nonetheless, births in this category are extremely important because of the high rates of morbidity and infant death and the high financial and social costs associated with these births. Even modest reductions in the rates of VLBW births can make prevention programs extremely cost effective.

In summary, this project demonstrates that current prematurity prevention strategies can be implemented for a wide segment of private and public patients on a regional basis. The program has been received enthusiastically by many private obstetricians and family physicians. These preliminary results suggest this model may be particularly effective in a private practice setting. Continued examination of these trends over a multiyear time span will be needed to confirm these results.

Further reductions in premature births could be accomplished by: (1) wider promotion and adoption of this risk assessment, educational, and intervention model; (2) efforts to ensure that prenatal care is available to all pregnant women regardless of income; and (3) further investigation about the causes of premature birth and, in particular, premature rupture of the fetal membranes.

Discussion

DR. WILLIAM N. P. HERBERT, Chapel Hill, North Carolina (Official Guest). Dr. Meis and colleagues have reported their experience with a project aimed at decreasing premature births over a wide geographic area of our state that encompasses almost 20,000 births per year. With the use of a combination of patient education of the signs and symptoms of preterm labor, prenatal risk assessment with close surveillance of high-risk gravid women, and prompt evaluation of all patients with excessive uterine activity, they found a downward trend in the rates of LBW and VLBW infants for both private and public births. In addition, they presented the substantial financial savings calculated from having fewer preterm infants delivered.

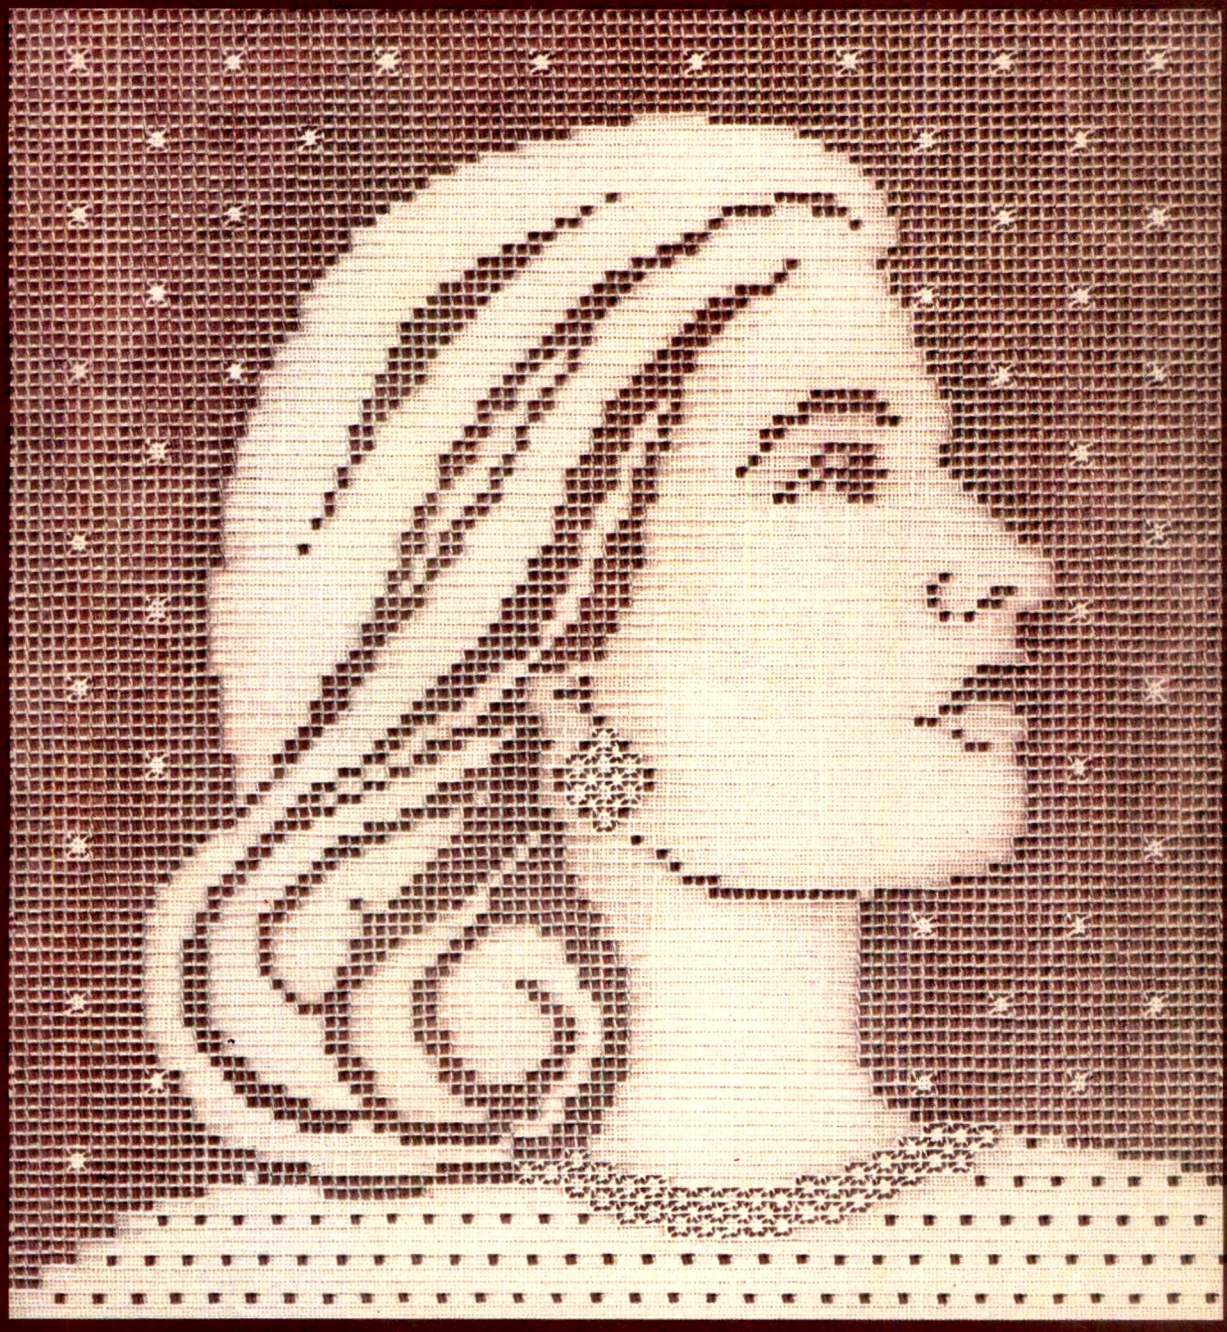
As noted by Dr. Meis, others who have addressed this issue have reported conflicting results. Papiernik et al.,[1] using a multifaceted approach, found a significant reduction in preterm births, most impressive in the earliest gestational age groups and in the lowest social groups. Interestingly, patients in the highest risk group did not show a reduction in the rate of preterm delivery. Herron et al.[2] have also noted an improved preterm delivery rate with such a program in a supposedly middle-class population in San Francisco, California. However, Main et al.,[3] utilizing an "inner city" population in Philadelphia, Pennsylvania, reported no benefit of a preventive program of this type. In reviewing this manuscript and pertinent literature to attempt to explain these different results, several issues emerge that concern the questions asked in such studies and the answers provided in them. I would like to ask Dr. Meis to comment on these issues, using his experience in this area.

First, in looking at preterm birth prevention projects, are the proper questions being asked? These programs are directed toward early detection of preterm labor,

presuming that prompt intervention can forestall delivery. However, as it has been shown that preterm labor itself is responsible for only about 30% of preterm births,[4] the real benefactors of these programs, that is, patients with idiopathic preterm labor, may be lost in the much larger group of patients with premature rupture of the membranes or one of a host of maternal-fetal problems associated with or necessitating early delivery. Outcome data on the entire population may mask the benefit in this select group. It seems that only by focusing on patients with preterm labor of unknown cause can we really evaluate a preterm birth prevention program as described.

Second, are the appropriate answers being provided in these studies? The standard practice of using either delivery before 37 weeks' gestation or an arbitrary LBW definition of <2500 gm (or <1500 gm for VLBW infants) provokes a yes/no response in data outcome tabulation that can interfere with meaningful analysis. Would not a shift upward in the mean birth weight—say, from 1500 to 1900 gm—or a shift upward in mean gestational age—say, from 30 to 33 weeks—be very important? Furthermore, we must remember that, as shown by Goldenberg et al.,[5] a seemingly small prolongation of gestation, even 1 week, can have a significant effect on ultimte survival of these infants. Dr. Meis has shown us that the savings in medical care costs can also be substantial. Thus we cannot forget the strong impact of even slight shifts as we analyze data from these studies.

Certainly, preterm births involve multiple factors, among them obstetric history and other historical events, early detection of uterine activity, and the state of the cervix. The ideal study with a population large enough to be meaningful with a control population worthy of comparison would be extremely difficult to design. Moreover, preterm birth prevention programs need time to show their real colors. Papiernik's program required 4 years to show an effect, for instance, and it would be extremely unfortunate to have programs lose their funding base and support because of this so-called type III error, that is, erroneous evaluation of a program that has not been adequately implemented.[6]



As complex as preterm labor appears, however, the enormous magnitude of the mortality and morbidity of preterm births should fuel our efforts to reduce this complication that we so often see. Dr. Meis and his coworkers are tackling this issue and their continued work will help to further our knowledge of this important subject.

Dr. Meis (Closing). Dr. Herbert's comments are pertinent and thoughtful and suggest several additional methods for future analysis of results. I would emphasize some of the problems in evaluating results of this or similar programs to reduce rates of preterm birth. These problems include the time needed to obtain results and the importance of evaluation of the VLBW category. The time required to obtain results is fairly substantial. Approximately 1 year is needed to recruit the help of health care providers to initiate the program. A second year will elapse from the time of patient enrollment at the first prenatal visit until results of their pregnancy outcome are available. Frequently some time will elapse before improvement in the results of these pregnancy outcomes is noted. As Dr. Herbert mentioned, Papiernik's study took 4 years before showing improved results. Most public health projects are funded on a 3-year basis and funding agencies will expect results within 2 years before considering an extension of the funding. The VLBW group, as we have indicated, is an important group to consider because of the especially high morbidity and mortality rates and the very high financial costs involved. In addition, concern has been expressed that prematurity prevention strategies may simply shift the births from a previable group up into this VLBW group. The need for large cohorts of patients and the difficulty of obtaining these cohorts in a randomized prospective trial in a single geographic area suggests that alternative experimental designs are needed.

An enduring pattern of excellence

LEVLEN™

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

The lowest total hormonal dose in a monophasic OC formula

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be aware of the complete prescribing information for this product. Please also see brief summary of prescribing information on the next page

BERLEX™ Dedicated to innovation in OB/GYN medicine

LEVLEN™ 28
LEVLEN™ 21

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

BRIEF SUMMARY

Each Levlen tablet contains 0.15 mg of levonorgestrel (d (-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.03 mg of ethinyl estradiol (19-nor-17 α-pregna-1,3,5 (10)-trien-20-yne-3,17-diol) (7 pink inert tablets are included in Levlen 28).

Indications and Usage—Levlen is indicated for the prevention of pregnancy in women who elect to use OCs as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only OCs have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. (The rates given for Pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only OCs are used), and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving OCs, since the drugs are more effective in preventing intrauterine than ectopic pregnancies.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination being performed.

2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

Information for the Patient—See patient package labeling.

Laboratory Tests—1. The pathologist should be advised of OC therapy when relevant specimens are submitted.

2. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs:

a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thryoid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis, Mutagenesis, Impairment of Fertility—See "Warnings" section #3, 4 and 5 for information on carcinogenesis, mutagenesis and impairment of fertility.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings." Because of the potential for adverse reactions in nursing infants from OC tablets, a decision should be made whether to discontinue the drug, taking into account the importance of the drug to the mother.

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis; pulmonary embolism; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; benign hepatomas; congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria; hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Levlen must be taken exactly as directed and at intervals not exceeding 24 hours.

Any time the patient misses 1 or 2 light-orange tablets, she should also use another method of contraception until she has taken a light-orange tablet daily for 7 consecutive days.

For full details on dosage and administration, see prescribing information in package insert.

BRIEF SUMMARY

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

February 1987

Careful surgical technique can reduce infectious morbidity after cesarean section

James B. Lyon, M.D., and A. Cullen Richardson, M.D.
Atlanta, Georgia

A total of 635 consecutive cesarean sections performed in private practices during the past 20 years are reviewed. In the course of this 20-year period, we have tried to alter gradually our surgical technique used for this procedure to conform to the principles of surgery developed by Halsted. The study is divided into three periods of time to examine the results of changes in technique. With the use of the standard definition of febrile morbidity (temperature of ≥100.4° F during any two 24-hour periods after the first postoperative 24 hours) the postoperative morbidity rate was 15% during 1967 to 1973, 5.4% during 1974 to 1979, and 0.7% during the period 1980 through 1986. Prophylactic antibiotics were used with decreasing frequency. It was clear that the reduction in morbidity was the result of the modifications in surgical technique. (Am J Obstet Gynecol 1987;157:557-62.)

Key words: Cesarean section, febrile morbidity, surgical technique, suture material

Infectious morbidity after cesarean section continues to attract much attention and study. A recent bibliographic search through the National Library of Medicine found more than 600 articles published during the past 15 years on the use of antibiotics either prophylactically or therapeutically to reduce infectious morbidity after cesarean section. No article could be found that addressed directly the effect of surgical technique on infectious morbidity.

Almost 100 years ago Dr. Wm. S. Halsted began teaching the principles of meticulous surgery. The gentleness in the handling of tissue, careful hemostasis, asepsis, and the precise approximation of layers are just as important today as they were then. Without these principles successful major surgery in the 1890s was impossible. Without these principles today, major operations such as cesarean section are still fraught with high rates of infectious complications. During the past 20 years an attempt has been made to translate the principles of meticulous surgical technique into practice when cesarean section is performed. A review of this 20-year experience forms the basis of this report.

Material

A total of 635 consecutive cesarean sections that we performed during the period from Jan. 1, 1967, to Dec. 31, 1986 (20 years), were reviewed. These sections were done as incidents in the management of 4040 private obstetric deliveries. The demographic characteristics of the practice population were fairly constant throughout the period and consisted of 70% white and 30% black, predominantly middle-class patients. The only demographic characteristic that changed during this 20-year period was patient age. The average age of the patient undergoing cesarean section was slightly more than 25 years in 1967 and was almost 30 in 1986.

Our cesarean section rate changed markedly during this 20-year period. It was at slightly more than 5% in 1967 and grew to almost 20% in 1986.

During the early years of the study, 68% of the cesarean sections were primary, and only 32% were repeat operations. With the increasing cesarean section rate, repeat operations have increased and now constitute almost 50%. Encouragement of vaginal delivery after cesarean section has been done only in the past 2 years and has had little effect as yet on the rate.

As this study was designed to determine to what extent surgical technique affects postoperative morbidity, particular attention was given to fine points of operative routines.

Certain practices were essentially constant throughout the 20-year period. The traditional methods of careful asepsis to include careful skin preparation before operation were followed throughout. Almost all operations were done through a Pfannenstiel incision. The uterine incision was transverse in more than 90%; vertical incisions were reserved for patients in whom the lower uterine segment was not well formed. Regional anesthesia was used in more than 90% of the patients in all three groups. The only difference was that in group 1 patients this was usually spinal anes-

Table I. Total number of deliveries and rate of cesarean section

	Group 1	*Group 2*	*Group 3*
Total deliveries (n)	1925	1625	1490
Cesarean sections (n)	135	203	297
Cesarean section rate (%)	7.0	12.5	19.9

thesia and in group 3 it was almost uniformly epidural anesthesia. Spinal and epidural anesthesia were used about equally in group 2.

Method

It was about 20 years ago when we began a diligent attempt to modify our operative technique in a large number of little ways. Every aspect of surgical technique was questioned, for example, the choice of suture material and needles for uterine and abdominal closure, the desirability of the use of transurethral catheters in the bladder and laparotomy pads in the abdomen, every minor aspect of tissue handling, and many other quite small to minute points of technique that might affect tissue reaction. Some changes were tried and abandoned. Those that were seen to be beneficial were retained. This has been an ongoing slow and continuing evolution. The changes that were made tended to evolve rather than to be invoked at a specific time.

However, in analyzing the results, it seemed appropriate to divide the 20 years into three time periods: 1967 through 1973 (group 1), 1974 through 1979 (group 2), and 1980 through 1986 (group 3). The first dividing line at the end of 1973 was chosen to conform to the beginning routine use of synthetic absorbable polyglycolic acid suture instead of catgut and silk, respectively, for closure of the uterine and abdominal incisions. The second division at the end of 1979 was chosen to conform to the change in the hospital in which we conducted our practice. All of our deliveries and cesarean sections from 1967 to 1979 were performed in a teaching hospital with residents as assistants. In late 1979, because of changes in the demographic features of our city, we moved our office and in turn we changed our hospital of practice to a private, nonteaching hospital with an obstetric service of approximately the same size. The anesthesia staff, operating room facilities, and level of asepsis appeared the same in the two hospitals. However, as there are no residents, all operations in the past 7 years have been done with the assistance of another fully trained practicing obstetrician-gynecologist. (Meticulous operation is more easily performed with experienced help.)

The size of each group with the cesarean section rate for each period is shown in Table I.

Twenty patients underwent planned cesarean hysterectomies at the time of repeat operation and four had unplanned emergency hysterectomies. They were equally distributed among the groups.

Comment

The rationale underlying our changes in technique was based on the concept that although bacteria are present in all wounds, their multiplication and growth require a culture medium of killed or damaged tissue with accompanying exudate and/or blood. This indicates that every possible attempt be made to reduce tissue damage. Our experience with the use of this approach for abdominal hysterectomy has been reported previously.[1, 2]

To develop a consciousness about tissue trauma, one must think at the level of the individual cell and rebel at the idea of killing or damaging even one cell unnecessarily. It is difficult to define objectively what to some might appear to be minor differences. A few examples with our reasons for the changes follow. At the beginning of the series, subcutaneous bleeders were clamped hurriedly with standard hemostats; today they are carefully clamped with mosquito hemostats. The smaller the number of fat cells destroyed by the hemostat, the less the amount of free oil and cellular debris left in the incision. In 1967, we routinely placed laparotomy pads into the paracolic gutters; today this is never done. Laparotomy pads can abrade serosal surfaces. In the 1960s, we always used an indwelling transurethral catheter in the bladder during operation, leaving it in place for 24 hours after operation; today the indwelling transurethral catheter is never used before, during, or after operation. A considerable percentage of urinary tract infection can be eliminated by omitting transurethral catheters. Until the late 1970s, scissors were frequently used to cut tissue; today all tissue is cut with a sharp knife. Scissors invariably pinch tissue apart and cause more trauma than a sharp knife.

Most of the many changes were similarly small, but all were intended to reduce the number of killed or damaged cells left in the patient as she went to the recovery room.

There have been several changes in suture material and needles used. Before the advent of polyglycolic acid suture in the early 1970s, the uterus was routinely closed with chromic catgut and generally the abdominal wall was closed with silk. Today polyglycolic acid sutures, of much smaller sizes and placed with much smaller needles (3-0 Dexon on a T-16 needle), are used for both. At the beginning of the period, interrupted 2-0 and 3-0 silk sutures were used to close the skin. Currently this is done with an intradermal suture of 6-0 polyglycolic acid suture (6-0 Dexon on a CE-2 needle). The synthetic absorbable sutures excite much less

tissue reaction than do catgut and silk. The larger the needle passed through tissue, the greater the trauma done to that tissue; thus the needle size has been decreased several times.

Another major change has been in the placement of sutures as close as possible to the edge of the layer being sewn. This results in a narrower wedge of and volumetrically a smaller amount of tissue within the suture line. Tissue within a tied suture has some diminution in blood supply and tissue perfusion.

Also, during the past 6 years, in closing the uterus no sutures are passed into the endometrial cavity. As long as a suture remains traversing the endometrial surface, the endometrial lining cannot reseal and the suture can have a wicking action, allowing the bacterial flora of the endometrial cavity constant upward access to the myometrium.

Prophylactic antibiotics have been used only in patients having primary operations and here with decreasing frequency as they seem to be unjustifiable from a cost/benefit analysis unless there appears to be infection present at the time of operation. There has been no hesitancy to use them postoperatively if there is any hint of infection as manifested by anything from a slight temperature elevation to faint erythema around the incision. Nevertheless, 29% of the patients in group 1 received some antibiotics, 25% in group 2, and 11% in group 3. In group 1, the antibiotic of choice was injectable penicillin with or without streptomycin. In group 2, the majority received oral ampicillin or injectable penicillin with or without streptomycin. In group 3, 29 of the 33 patients given antibiotics received oral ampicillin or injectable penicillin, two patients received cefoxitin, one received cefazolin, and one, oral erythromycin. In only 10 (3.4% of the Group 3 patients) were the antibiotics begun prophylactically at the time of operation.

No attempt was made to culture the uterine contents unless infection was suspected at the time.

Results

There has been a progressive reduction in postoperative morbidity. Table II shows the febrile morbidity, defined in this study as temperature of ≥100.4° F (38° C) in any two 24-hour periods after the first postoperative day. Also shown is the length of postoperative hospital stay.

There have been only two patients with febrile morbidity among the 297 group 3 patients: One had severe pregnancy-induced hypertension with convulsions (eclampsia) and the other had a placenta accreta, in which the placenta required removal by sharp dissection with some attendant myometrial damage and resultant endomyometritis. The patient with eclampsia did not receive prophylactic antibiotics. The patient with placenta accreta received cefoxitin at the time of operation. Neither had any temperature recording above 101.8° F, and both recovered promptly with postoperative hospital stays of 7 and 6 days, respectively.

Table II. Febrile morbidity and length of stay after cesarean section

	Febrile morbidity (%)	*Postoperative stay (days)*
Group 1	15.0	4.9
Group 2	5.4	3.8
Group 3	0.7	3.5

The blood transfusion rates were between 4% and 5% throughout the 20 years, with no significant difference between the three groups of patients. The cesarean hysterectomies had no effect on morbidity rates but did influence the rate of transfusion as more than half of them required some blood replacement.

All patients in the series have been seen at least once in the office for postoperative follow-up at 4 to 6 weeks post partum (most have been followed up for years). No pelvic abscesses were detected in any patient in the entire series. There were three incisional hematomas requiring drainage in the office among the group 3 patients and two in group 2. (No hematomas were recorded in group 1.) None of these patients was febrile. There were no incisional abscesses or disruptions. Only one patient (from group 2) became febrile after discharge and required readmission to the hospital. She had a small broad ligament hematoma. She responded promptly to antibiotics without drainage.

All of the morbidity in groups 2 and 3 occurred after primary cesarean section. There has been no morbidity in more than 200 repeat operations and none of these patients received prophylactic antibiotics. No consistent relationship was found between morbidity and the number of vaginal examinations, internal fetal monitoring, length of time of ruptured membranes before cesarean section, or type of anesthesia.

There were no maternal deaths. There was one serious complication in this series in a group 2 patient. The cesarean section was done in this patient because of failure to progress in labor with twins. The operation was begun with the patient under epidural anesthesia with the delivery of two healthy infants. During the closure of the abdomen, the anesthesia in the abdominal wall began to fade and the anesthesiologist elected to switch to light general anesthesia. The patient was given pentothal sodium and a bolus dose of succinylcholine. Almost immediately the patient had tonic contractions of all muscles and shortly thereafter began to manifest signs of malignant hyperthermia. In spite of very aggressive treatment, the body temperature rose

above 108° F. She sustained severe central nervous system damage.

It might appear that with the large increase in cesarean section rate there has been only a dilution of the so-called inevitable sepsis in this group of patients. However, when one divides the number of cesarean operations associated with sepsis by the number of deliveries during each period, it is apparent that 0.88% of the obstetric patients in group 1 were morbid as a result of cesarean section; in group 2, 0.68% were morbid as a result of cesarean section; in group 3, 0.13% experienced morbidity as a result of cesarean section.

The only negative result of this approach was, as might be suspected, a slight prolongation in operating time. As one becomes more meticulous, additional time is required to perform the operation. At present the usual operating time is between 50 and 75 minutes. With larger needles and sutures and big bites of tissue, the operating time was much shorter.

Comment

Danforth,[3] in an excellent review article in 1985, gave the prevailing morbidity rates for cesarean section as 50% to 65% without prophylactic antibiotics and 15% to 26% with antibiotics. Duff and Kopelman[4] in a similar review article reported febrile morbidity rates of 44% without and 20% with prophylactic antibiotics.

There are difficulties in comparing an all-private patient study with studies of large numbers of indigent patients. Danforth in his review cited two Swedish studies[5, 6] that he felt might conform to the clientele of the average U.S. obstetrician in private practice. In these two series, prophylactic antibiotics were not used, and their rates of postoperative infection were 13.3% and 20%, respectively. Anstey et al.[7] in an all private patient study at St. John's Mercy Hospital in St. Louis, Missouri, reported a morbidity rate in primary cesarean sections of 23% without prophylactic antibiotics.

In one of the few recent articles that did not advocate prophylactic antibiotics, Iffy et al.[8] were able to show that with traditional preventive measures such as careful aseptic technique the infection rate after cesarean section was gradually reduced from more than 80% to 16.2%, without prophylactic antibiotics. Throughout the period of our study, we have tried at all times to follow the principles advocated by Iffy.

Ledger[9] reported the incidence of postpartum endometritis after abdominal delivery as being 10 times greater than that after vaginal delivery. Presumably the bacterial flora is similar in the two groups. The only difference is the incisions in the abdominal wall and uterus. With meticulous handling of these incisions, the ratio theoretically could be 1 to 1, not 10 to 1.

In the present study, the progressive decrease in febrile morbidity has been a significant one. The decrease in this series of patients is largely attributed to the changes in surgical technique–not better antibiotic prophylaxis, as antibiotics were used with decreasing frequency. The morbidity reduction from group 1 to group 2 seemed to be principally due to the change from catgut to polyglycolic acid suture. Refinements in tissue handling and suture placement and smaller suture and needle size seemed to be responsible for the additional improvement between groups 2 and 3.

In association with the decreasing morbidity, the patients were observed to have a generally smoother postoperative course with a resultant decrease in the postoperative hospital stay. In the last 297 (group 3) patients, the range in postoperative stay was 2 to 7 days; the average was 3.5 days.

To achieve the 0.7% morbidity rates reported in the last 297 cesarean sections, we pursued no new or special program. Nothing was done other than an attempt to be constantly aware of avoiding tissue trauma in every minute way possible. It was apparent to us that these little things made a difference in how well the patient fared after operation. The development of a consciousness regarding tissue trauma was a gradual evolution over the 20 years. It is our intention to continue to refine further this approach with the hope that we will be able to maintain morbidity rates of under 1%.

This study supports Halsted's century-old teachings that undamaged tissue can withstand very significant bacterial insult. Apuzzio and Iffy,[10] in an excellent book chapter on perinatal infection control, remarked after discussing Semmelweis' work: "Contemporary physicians are trained to believe that the progress of medicine is so rapid that research conducted a few decades ago is obsolete. . . . If infection control is to be effective and meaningful, any control measure must be proven to be unnecessary before it is abandoned." The same would apply to Halsted's teachings regarding surgical technique.

All wounds are contaminated—the cesarean section may be more so, yet undamaged tissue can withstand most of this contamination.

As indicated, the meticulous approach requires additional operating time, but as this study indicates the time is well spent.

Discussion

DR. ROBERT M. WEIN, Greensboro, North Carolina (Official Guest). This report is an introspective evaluation of one group's 20-year experience with cesarean section and its associated febrile morbidity. The principles discussed should be widely held in all surgical procedures. Minimal tissue trauma, proper suture choice, good hemostasis, and asepsis do result in less febrile morbidity, fewer complications, quicker postoperative recovery, and shorter hospital stays, as Lyon et al. have shown.

For the purposes of comparison, to allow discussion, and to look at febrile morbidity in a slightly different perspective, all cesarean sections done at Moses Cone Hospital in Greensboro, North Carolina, between October 1, 1985, and September 30, 1986, were reviewed. During this 12-month time period, 943 cesarean sections were done: 80% were done on private patients by one of 24 attending obstetricians, and 20% were performed in teaching service patients where a resident was often assisted by an attending doctor. Overall, 69% of the cesarean sections were primary and 31% were repeat operations. According to the standard definition of febrile morbidity, the febrile morbidity rate was 2.6% on the private service and 9.7% on the teaching service. The total combined febrile morbidity rate was 4.0%. This corresponds very favorably to previously published figures, although it does not reach the 0.7% rate of Lyon et al. in the last 7 years of his 20-year review.

There are some other apparent differences in Dr. Lyon's group and our group. In our group, prophylactic antibiotics were used 81% of the time and usually consisted of one to three doses of a first-generation cephalosporin begun immediately after the umbilical cord was clamped. Objective evaluation suggests underuse by some of our obstetricians and overuse by others. In a comparison of individual practices, using prophylactic antibiotics 100% of the time did not result in the lowest individual febrile morbidity rates. On the other hand, 29% of our febrile morbidity occurred in the 19% of patients that did not receive prophylactic antibiotics. The use of antibiotic prophylaxis for women in labor requiring cesarean section may be appropriate.

Lyon et al. stressed the decreasing frequency of use of prophylactic antibiotics in his series. Certainly one cannot argue with their results without the use of prophylactic antibiotics. In their group 3, only 11% (33 of 297) received antibiotics; in 21 they were not given prophylactically but rather in response to "any hint of infection," and these 7% did not go on to satisfy the standard definition of febrile morbidity. Indeed the use of antibiotics can alter the febrile morbidity rate, which by definition requires a temperature >100.4° F occurring in two separate 24-hour periods after the first 24 postoperative hours. In fact, in our series, endometritis was diagnosed in 11 patients who once they were begun on a therapeutic regimen of antibiotics responded so well that they did not fit the standard definition of febrile morbidity. It may be more accurate to compare actual clinical situations such as endometritis, wound infection, or pelvis abscess rather than to use a strict definition depending only on temperature.

Lyon et al. emphasized the use of polyglycolic acid suture instead of catgut in closure of the uterus and abdomen to effectively lower postoperative febrile morbidity. In addition, attention to minimal tissue trauma by use of smaller gauge suture and smaller needles was discussed. The mechanics of polyglycolic acid suture breakdown in tissues by hydrolysis as compared with phagocytosis in catgut suture breakdown clearly establishes polyglycolic suture as less reactive. Interestingly, in our series, 21 of 26 (81%) patients developed postoperative endometritis after uterine closure with catgut suture. This is probably significant as 66% of our total group had uterine closure with catgut. This would support Dr. Lyon's thesis.

All of our patients undergoing cesarean section had a transurethral Foley catheter placed before operation, usually as part of the surgical preparation, and these catheters were removed on the first postoperative day. There were only seven urinary tract infections in the 943 patients and this low rate is probably related to our 81% prophylactic antibiotic usage. This is one area deserving of more comment by Dr. Lyon, in that he stated that an indwelling, transurethral catheter was never used before, during, or after operation. With the large amount of intravenous fluids given preoperatively and intraoperatively, especially when regional anesthesia is used, with procedures lasting between 50 and 70 minutes, and considering patient immobility after operation, it is difficult to imagine not using a catheter to keep the bladder decompressed during surgery to avoid bladder injury, to allow a true low transverse cesarean section to be done, and to aid in drainage in the immediate postoperative period.

Operative time at our hospital averaged 40 minutes. This ranged from an average of 25 minutes to 56 minutes for individual attending physicians and did not correlate with specific rates of febrile morbidity.

Our postoperative hospital stay averaged 3.5 days, exactly what Dr. Lyon noted in group 3. This is really an important figure brought out by these discussions.

This is the end result of our efforts as viewed by third-party payers.

Dr. Lyon's presentation should be taken as a personal challenge to each of us as it applies to our surgical techniques. This is the age of increasing demand for better results and cost-effective methods. Attention to details of surgical technique, operative routines, suture choice, and asepsis take only time and thought. We cannot depend on antibiotics to cover poor technique. It is incumbent on each of us to take Dr. Lyon's messages home and apply them in our practices.

Dr. Ralph A. Tillman, Lawrenceville, Georgia. I would like to ask Dr. Lyon one question. Do they use the Bovi for hemostasis at all at Piedmont Hospital? It certainly has been my experience that quite frequently the overuse of the Bovi is the cause of postoperative morbidity. I would like to hear a comment on that.

Dr. Edgar C. Garber, Jr., Fayetteville, North Carolina. I have not been an active obstetrician for many years but I still deal with the residents. I try to preach three things in the operating room on cesarean section and I am not very successful. Number one is expression of the placenta. As soon as the baby is delivered a resident is trying to remove the placenta. A small bolus of oxytocin will separate the placenta with very little blood loss. Second, it seems the residents cannot sew up the uterus unless it is out of the abdomen. They exteriorize the uterus, which exposes it to the room air and respiratory infections of the operating room personnel. It also places a lot of stretch on the vessels. Third, as Dr. Lyon already mentioned, the technique of closure of the uterus is important. In closing the endopelvic fascia the residents tend to use large bites and elaborate stitches with 1-0 chromic catgut. I feel this is a very timely article and I appreciate its presentation.

Dr. Lyon (Closing). Dr. Wein, thank you for your fine discussion and also for a demonstration of what a good private obstetric service can accomplish in reducing post–cesarean section morbidity. One difficulty in evaluating results is the lack of information about private obstetrics in the United States. We need enough statistics from all over the country to set standards for private service, but from what we know now your rate is excellent.

The bladder certainly does fill during the procedure and it is drained with a 16-gauge needle attached to the suction device inserted into the bladder in any retroperitoneal area. This is done as often as necessary and at closing to prevent overfilling before complete recovery from the epidural anesthetic. If the patient cannot void in the early postoperative period, a small straight catheter is used, but less than 10% of patients will require this even one time.

Postoperative hospitalization is affected by many factors in obstetric patients. Most of our patients could leave the hospital on the second postoperative morning if physical recovery alone was considered. It has been obvious that as our technique has improved postoperative recovery has become very rapid.

Thank you, Dr. Tillman, for your raising the question of Bovi hemostasis. There is no question that using the Bovi in our patients causes much more tissue reaction in the incision and subcutaneous tissue than ligation of individual vessels with fine suture. We have compared this in different patients and on different sides of the same incision. I confess though, in the interest of speed, we often use the Bovi and try to leave the smallest possible burn on the vessel.

Introduction by Dr. Leo Dunn

I am very pleased to introduce to you an old friend and distinguished colleague of mine, Dr. Henry A. Thiede, who is well known in the South for his years of Chairmanship at the University of Mississippi and in the North for his Chairmanship at the University of Rochester, where he followed Dr. Curtis Lund, one of the best known and most beloved individuals in our specialty. Dr. Thiede has carried on the traditions of teaching that Dr. Lund and his colleague John Donavan began at that institution many years ago. Dr. Thiede has served in many important positions in our specialty. He has been Director of the American Board of Obstetrics and Gynecology. He sits on the Board of Emergency Medicine. He has been a past Chairman of the Residency Review Committee and he has now taken the position of Dr. Mattingly as the Secretary of the American Gynecological and Obstetrical Society. Dr. Thiede, we apologize for all the difficulty that you had in coming here but we look forward to your comments this morning.

Urogynecology: Comments and caveats

Henry A. Thiede, M.D., and Vasant D. Saini, Ph.D.
Rochester, New York

Historically, the routine workup of the incontinent woman has focused on clinical parameters including history, pelvic examination, cotton swab test, and radiographic imaging of the bladder and urethra. Data are presented to support the concept that urinary symptoms and pelvic findings do not accurately define the causes of incontinence. Because urinary incontinence is both a dysfunctional and a structural problem, evaluation of the urodynamic response of the lower urinary tract should be part of the workup of the incontinent woman. (Am J Obstet Gynecol 1987;157:563-8.)

Key words: Stress incontinence, urodynamics, urethral closure pressure

Countrywide, most obstetrician-gynecologists employ clinical and anatomic assessments as the only means for establishing the diagnosis and deciding the treatment of women with the complaint of urinary incontinence. The problem is that female urinary incontinence is the result of abnormal function that may only coincidentally be associated with, but not necessarily caused by, abnormal pelvic support. There are a number of different reasons for stress incontinence that have no relationship to anatomy per se. We hope the examples presented here will help encourage more physicians to pursue a functional evaluation of the lower urinary tract in addition to the traditional structural evaluation.

Table I. Urodynamic diagnosis of 200 women with urinary incontinence

Diagnosis	*No./%*
Genuine stress incontinence only	132/66
Detrusor instability only	28/14
Both genuine stress incontinence and detrusor instability	36/18
Other	4/2
Total	200/100

Methods and material

Two hundred women were referred to the Urogynecology Laboratory in the Obstetrics-Gynecology Department for symptoms of urinary incontinence. All patients were evaluated similarly and the data were entered on-line into an elaborate computer program described elsewhere.[1] An extensive urologic and medical history was obtained similar to that described by Ostergard.[2] Pelvic and neurologic examinations were recorded. Residual urine, urethral angles, urinalysis, urine culture, and a 24-hour voiding diary were routinely obtained. Simultaneous continuous pressure recordings of the bladder, urethra, and vagina were dis-

played on a six-channel recorder (Disa 2100 Urosystem, Dantek Elektronik, Skovlunde, Denmark) and stored on an IBM XT computer using 8F microtip catheter transducers (Millar Instruments, Inc., Houston, Texas). The bladder was filled retrograde at 30 ml/min with sterile saline solution at 37° C. Urethral pressure profiles and resting and stress pressures were obtained at ≤100 ml in a supine position, 250 ml in a supine position, full in a supine position, and sitting erect, full with the transducer oriented to 3 o'clock. Standing pressures were obtained when indicated. Monitored and unmonitored uroflow curves were recorded; CO_2 urethroscopy with filling at 150 cc/min was performed during the same visit.

Results

The urodynamic diagnoses for the 200 incontinent women are listed in Table I. Comparison of the urinary symptoms in each of the diagnostic groups reveals that although some symptoms occur significantly more often in one group than in another, there is so much overlap that it is clear that symptoms alone cannot define a specific diagnosis for urinary incontinence (Table II). Similarly, in Tables III and IV, although the degree of cystocele and the urethral axis are significantly different ($p = <0.01$) in patients with only genuine stress incontinence when compared with patients with only detrusor instability, there is so much overlap that these observations are also of little value as tools for making a definitive clinical diagnosis.

Six patients have been selected to illustrate the importance of a urodynamic evaluation (Table V). The first two patients have a normal pelvic examination and a normal cotton swab test. S. B. (Table VI) is continent. Note, however, that in spite of her normal anatomic structure she does demonstrate a marked decrease in urethral closure pressure with Valsalva. She maintains continence because the high resting closure pressure provides a tolerance that keeps the stress closure pressure above zero and the urethral sphincter mechanism responds appropriately to filling and position change as seen in the steady level of maximum resting closure pressure. In spite of normal pelvic support, F. C. (Table VII) has genuine stress incontinence. Note the consistently low urethral closure pressure and functional area, which are maintained with bladder filling and moving to an erect position. Because she has a negative stress pressure ratio,* with the low resting urethral pressure, the urethral closure pressure drops below zero with cough or Valsalva and urine escapes. Because

*For the purpose of this presentation, a negative stress pressure ratio is a urethral pressure/bladder pressure that is <1.0. A positive stress pressure ratio is ≥1.0.

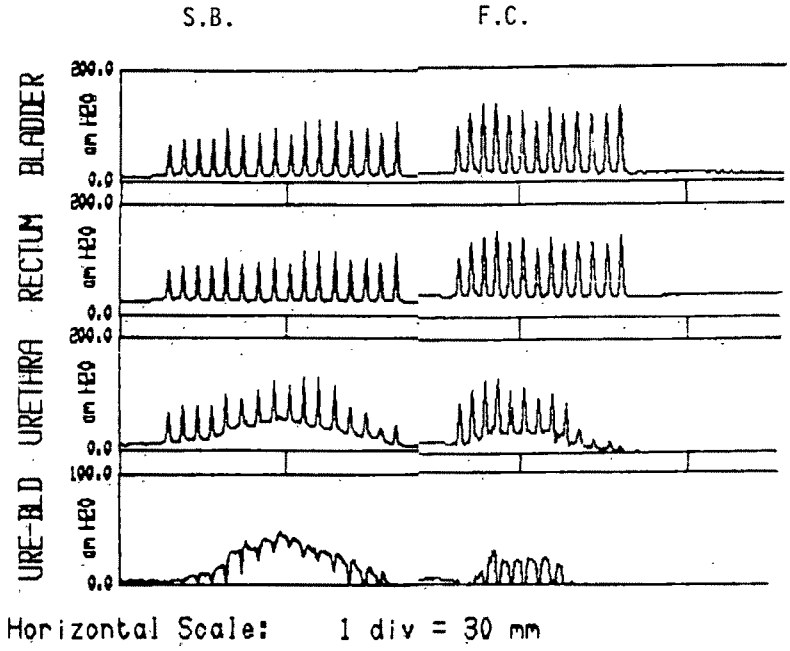

Fig. 1. The area under the curve in the URE-BLD channel of these stress urethral pressure profiles indicates the relative margin of continence. S. B. is continent; F. C. is not.

Table V. Patient summaries

there is no anatomic relaxation and the urethrovesical junction is maintained in its normal abdominal position, the negative stress pressure ratio is the result of an inadequate response of the components of urethral pressure (i.e., the striated and smooth muscle and possibly also the submucosal vascularity). The inadequacy of these components also accounts for the low urethral closure pressure. The stress urethral pressure profiles for these two patients are seen in Fig. 1. Note that in the incontinent patient (F. C.) there is no functional area above zero in the urethral closure pressure *(URE-BLD)*.

Both of the two patients in the second set have an abnormal cotton swab test result but no significant cys-

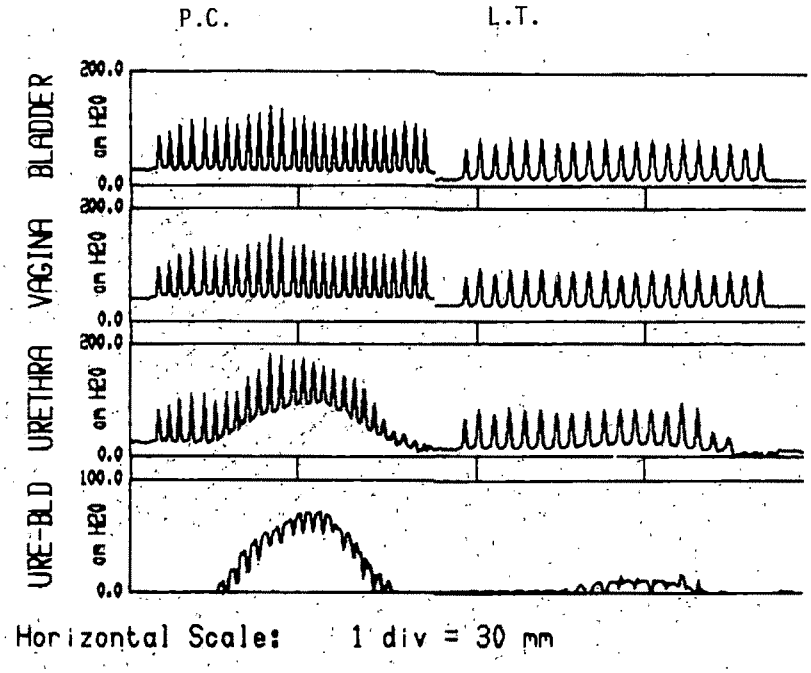

Fig. 2. These stress urethral pressure profiles illustrate the significance of a high urethral closure pressure. P. C. is continent; L. T. is not. Both have significant loss of pubourethral support.

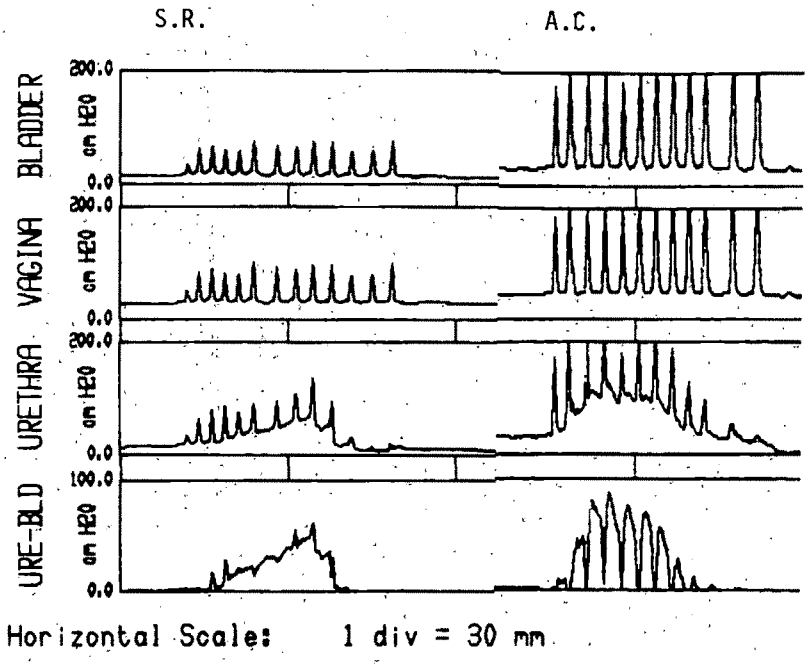

Fig. 3. The stress urethral pressure profile for S. R. is consistent with significant urethral funneling. In spite of a good urethral closure pressure, the amplitude of the stress and the loss of sphincter competence cause A. C. to be incontinent.

tocele. P. C. (Table VIII) does not lose urine in spite of loss of pubourethral support and a negative stress pressure ratio. This is because she has a high urethral closure pressure and maintains a steady functional urethral area during filling and position change. This gives her a large margin for a drop in closure pressure with stress. On the other hand, L. T. (Table IX) has a low resting urethral closure pressure and a functional urethral area that drops further during filling and position change, giving her no tolerance for the decreased pres-

sure in the urethra with stress; hence, significant stress incontinence occurs. The stress urethral pressure profiles for these two patients are seen in Fig. 2. In L. T. there is hardly a perceptible tracing in the subtracted channel *(URE-BLD)*.

The last two patients have both an abnormal cotton swab test result and a moderate (second degree) cystocele. Both patients have normal closure pressures that are maintained with filling and position change. However, S. R. (Table X) maintains a functional urethral area and also has a positive stress pressure ratio in spite of her anatomic defect. Additionally, her urethral pressure profile is consistent with urethral funneling, which was subsequently demonstrated on a voiding cystourethrogram. She maintains urinary continence in face of the anatomic defect because the urethra is a dynamic structure and the elements compromising her urethral pressure reacted positively to the sudden increase in abdominal pressure. On the other hand, A. C. (Table XI) has some attrition of the resting functional urethral area with filling because of shortening of the functional length of the urethra. Although it is a symmetric urethral pressure profile, note the marked negative stress pressure ratio that is the result of the very large increases in intra-abdominal pressure and the inability of the urethra to compensate functionally for this with leakage as a result (Fig. 3).

Comment

Cardozo and Stanton[5] found that urinary symptoms and the degree of pelvic relaxation do not discriminate

Table XII. Elements of urinary continence detectable only by urodynamic evaluation

patients with genuine stress incontinence from patients with detrusor instability. In their prospective study of the cotton swab test, Fantl et al.[4] found that assessment of the urethral axis was not predictive of urethral function. The six cases reported in this study also illustrate that it was not the anatomic support but the ability of the urethra to respond to sudden increases in abdominal pressure and the level of tolerance in urethral closure pressure that determined continence. Table XII lists factors that affect continence but are not apparent except by urodynamic evaluation.

Urodynamic workup often uncovers genuine stress incontinence resulting from caffeine abuse, hypoestrogenic atrophy, urethrocystitis, prescription drugs such as phenothiazines, antihistamines, and calcium channel blockers, and neurologic disorders, to name a few. Any of these may affect the ability of the urethra to respond

appropriately to a sudden increase in abdominal pressure or may contribute to a low resting urethral closure pressure, which lowers the tolerance for any significant negative stress pressure ratio. If present, anatomic relaxation can be merely coincidental; surgery certainly is not the primary treatment under those circumstances.

Urodynamic studies that do not include simultaneous monitoring of urethral, bladder, and abdominal pressures and the capability of reading urethral closure pressure and detrusor pressure (as opposed to bladder pressure) are likely to be misleading. There is no room for shortcuts; no single urodynamic study or parameter has been found that can give a reliable diagnosis. Compulsive attention to many details is essential for the urodynamic results to be valid, and the studies probably should not be undertaken by the occasional participant.

Having said that, it is also important to state that urodynamic techniques and interpretations are still evolving; the reproducibility, sensitivity, and specificity of some aspects have yet to be evaluated. Urodynamics is a rapidly growing research area that lends itself to the application of the sophisticated new technology that is becoming available. However, even in its present form it is a valuable if not essential tool for the clinician in the workup of urinary incontinence.

We gratefully acknowledge the contributions and assistance provided by Alean Fullerton, B.S.N., Kathy Schwarz, R.N., M.S., and Florence Thiede, B.S.N.

Necrotizing fasciitis of the vulva

David B. Roberts, M.D.
Columbus, Georgia

Sixteen cases of necrotizing fasciitis arising from or involving the vulva are presented. Fifteen of the 16 women had diabetes mellitus. Five of them died. All but one of these cases were managed by very extensive excision of all involved tissues. These cases demonstrate the extreme seriousness of any infection involving the vulva in a diabetic patient. Such patients should have the infected area explored while they are under anesthesia as soon as possible. If any necrosis is found, radical excision to include removal of all necrotic, indurated, and pale tissues is mandatory. (AM J OBSTET GYNECOL 1987;157:568-71.)

Key words: Necrotizing fasciitis, synergistic bacterial infection, diabetes mellitus, radical excision

Necrotizing fasciitis is a rapidly progressive, highly toxic, often fatal, and commonly synergistic bacterial infection. Usually, it arises after minor trauma or an insignificant-appearing infection. Necrotizing fasciitis, as a complication of infections of the vulva and perineal region, is fortunately quite rare.

The initial signs of necrotizing fasciitis are erythema, edema, and localized pain. When areas of dark discoloration, bullae, or obvious skin necrosis develop, there will always be extensive underlying necrosis and the infection may spread quickly along fascial planes with resultant necrosis of large areas of the body. Diabetic patients with any abscess or infection of the vulva or perineal area need immediate hospitalization and aggressive surgical management. When there is evidence of necrosis, incision and drainage and antibiotic therapy are insufficient treatment. Although reports of necrotizing fasciitis in other areas of the body do not indicate that diabetes mellitus is an integral part of the pathogenesis of the disease, diabetes mellitus is nearly always present in the patient with necrotizing infections involving the vulva.

Historical review

In 1926 Brewer and Meleney[1-3] reported two cases of progressive gangrenous infection of the skin and subcutaneous tissues that occurred in and around abdominal wounds after operation for acute perforative appendicitis. The wound infections were stated to resemble carbuncles; the skin edges had early necrosis, and the skin was undermined with rather extensive necrosis. The first patient was treated by creation of a deep circumferential incision that enclosed the diseased area, and the encircling wound was packed. The enclosed area sloughed, but the infection did not extend beyond the barrier. The second patient was cured by wide excision of the area of infection and necrosis. Animal cultures showed that the infection was synergistic and that one organism alone was not able to produce the progressive necrosis seen in the two patients. Their study also provided the basis for management.

In 1952 Wilson[4] reported 22 cases of necrotizing fasciitis at Parkland Hospital in Dallas, Texas, and found that, when probing demonstrated undermining, immediate surgical treatment was indicated. He stated: "... to postpone surgery and use massive doses of antibiotics is ineffective." In 1972, Roberts and Hester[5] reported six cases of necrotizing fasciitis involving the

vulva, all in diabetic women. In that series of cases three of the four patients whose initial surgical procedure was incision and drainage or debridement died, while the other was left disabled. Two had wide excision as the initial surgical procedure, and both were cured. The authors concluded that "Patients with diabetes mellitus, regardless of severity, and abscesses of the vulva or Bartholin's gland duct must be considered to have necrotizing fasciitis until proved otherwise. Such patients should have the vulva explored under anesthesia, and, if tissue necrosis is found, radical excision to include removal of all necrotic and indurated tissues be performed . . .."

Patient review

Sixteen additional cases of necrotizing fasciitis involving the vulva are presented (Table I). Only one patient was not diabetic. Fourteen presented with either a history of diabetes mellitus or had an elevated blood glucose level at the time of admission. Patient No. 11 had an initial blood glucose level of 94 mg/dl but soon required insulin.

Most of the patients were not aware of the origin of the infection, although some began as Bartholin's gland duct abscesses. There were five deaths and these deserve review. In Case No. 5, the patient was managed initially in the emergency room where she had incision and drainage of a Bartholin's gland duct abscess. Five days later she was admitted in ketoacidotic coma with extensive necrosis of the skin and subcutaneous tissues of the lower abdominal wall, both sides of the groin, the entire vulva, the right buttock, and the entire right leg. She initially had rapid improvement in the blood glucose level, became alert, and seemed to respond to radical excision of the skin and subcutaneous tissues of the lower abdomen, radical vulvectomy, and disarticulation of the right hip. She then died of a sudden cardiac arrhythmia. In Case No. 6, the patient apparently had a myocardial infarction and collapsed in a bed of fire ants. When found she was unconscious and had extensive necrotizing fasciitis of the right labium, groin, and medial thigh. She died 2 days after admission and subsequent radical excision of all involved tissues. Autopsy results revealed myocardial infarction and necrotizing enterocolitis. In Case No. 10, the patient died of sepsis in spite of early extensive debridement and multiple-agent antibiotic therapy. In Case No. 11, the patient developed renal failure and died of azotemia and sepsis. Stone and Martin[6] reported nearly a 100% death rate in their diabetic patients with severe renal disease. In Case No. 15, the patient died suddenly, apparently of a pulmonary embolus, after nearly complete healing of the wound.

Case No. 16 is worthy of review as fascial and subcutaneous necrosis were found to involve the entire vulva, both sides of the groin, both buttocks and both legs, the trunk, and both axillae. Extensive debridement of areas of necrosis of the vulva and groin was performed. The patient was treated with multiple antibiotics and recovered even though the involved areas could not be surgically removed.

Bacteriology

Seven cases had more than one organism cultured from the areas of involvement (Table II). Many of these patients had been treated with antibiotics prior to being diagnosed as having necrotizing fasciitis, which probably interfered with efforts to obtain accurate data. The progressive necrosis seen in these cases is consistent with the belief that these are synergistic infections.

Comment

Necrotizing fasciitis involving the vulva is thought to be rare but 16 cases from a community hospital are reported, suggesting that the entity occurs more frequently than previously expected. Of the 22 patients presented in my two articles, all were adults and all but one had diabetes mellitus. Necrosis is a late sign and by the time skin necrosis is present the underlying liquefaction necrosis will have involved a very large area.

Initially, necrotizing fasciitis may appear as a simple abscess, but in the compromised patient this appearance is deceptive. Obvious necrosis is a late sign; by the time skin necrosis is present the underlying necrosis will have extended and involve far more tissue than is evident from examination. Systemic signs of toxicity are a late feature. No one group of bacteria is responsible for this disease, and the disease can be caused by almost any aerobic or anaerobic pathogen, either alone or synergistically.

Prompt recognition, resuscitation, immediate operation including complete and wide excision, antibiotic therapy, and multisystem support can be lifesaving. Excision should include removal of all diseased tissues until bleeding is encountered. Any tissues that do not have a pink color suggesting good capillary perfusion should be removed. The wounds can be managed most efficiently by leaving the defect open. Wounds can later be skin grafted and covered by a rotational flap graft; if kept clean the wounds will gradually close with a very narrow scar that often will give the appearance of a primary closure.

Discussion

Dr. Henry A. Thiede, Rochester, New York. The mortality rate in Dr. Roberts' series of 16 cases is 31% which compares favorably with the much higher mortality rates of other series. Early diagnosis makes the difference, but this is sometimes difficult, even if necrotizing fasciitis is under consideration. The overlying skin varies in appearance. It may be red or pale or cyanotic with bullae and gangrene. The margins may be distinct or vague. In advanced disease there is extensive undermining of the skin and a four-smelling sanguineous discharge sometimes described as "dishwater" in appearance. The superficial and deep fascia can be separated easily and appear stringy and gray-green in color. In the early stages of the disease, when cure is most likely, these findings may not be so dramatic. The use of frozen-section biopsy of the fascia to make a definitive diagnosis in the early evolution of the disease is championed by some and is worthy of consideration.

Survival in patients with necrotizing fasciitis of the vulva depends on early, extensive and complete debridement of the necrotic and infected tissues. An addendum to Dr. Roberts' fine description of the surgical management is the need to examine the operative area thoroughly, about 24 hours after the initial debridement, for any areas of persistent necrosis that may have escaped notice or developed in the interim. It is often necessary to anesthetize the patient again to effect this examination. Given that the patient may very well be prostrate from sepsis, this can be a difficult but important decision. Continued close observation of the wound is necessary. There is no conclusive evidence that topical antibiotics or wet dressings, dry dressings, or honey dressings are significantly superior. Amniotic membranes have been used as a temporary wound dressing in large defects. The effectiveness of hyperbaric treatment and hyperalimentation in these patients is still under study.

This paper deals with necrotizing fasciitis of the vulva and stresses that it is a diagnosis to be excluded in any diabetic patient with a vulvar infection. This is a good concept. However, obstetrician-gynecologists may be seeing more of this entity as a postoperative complication with an aging population that has arteriosclerosis and other chronic debilitating diseases, such as cirrhosis, renal failure, cancer, and malnutrition, that compromise host defenses. We are also seeing a growing number of younger women with drug dependency and immunosuppression caused by human T-lymphotropic virus type III, all of which are thought to predispose patients to an increased risk of necrotizing fasciitis. Cases have been reported after laparoscopy, abdominal hysterectomy, episiotomy, and vulvectomy. Moreover, the newborn infant is no exception as necrotizing fasciitis has been described as a complication of omphalitis, urachal anomalies, and necrotizing enterocolitis.

The compromised host defense also impacts on the selection and use of antibiotics. Like Dr. Roberts, most authors report mixed infections. For many years it was taught that necrotizing fasciitis was the result of a synergistic infection between hemolytic staphylococci and anaerobic streptococci. While these organisms are frequently present, gram-negative enteric bacteria and *Bacteroides* are also frequent isolates. *Clostridium* is occasionally present.

Cultures are important in selecting the correct antibiotic therapy. However, until the isolates and their sensitivities are reported, usually an interval no less than 48 hours, it seems appropriate to start the patient initially on a regimen of broad spectrum therapy such as a penicillin or cephalosporin, gentamicin and clindomycin, or metronidazole. A gram-stained smear of the exudate may occasionally give an early indication before culture of the presence of clostridium and should be routine.

As important as antibiotics and intensive care are, only an occasional patient survives if extensive debridement of the necrotic and infected tissue is not effected promptly. This and early diagnosis, which is usually the result of a heightened awareness of the disease process, will save lives. We thank Dr. Roberts for his contribution to this literature.

Outcomes in patients with unusually high maternal serum α-fetoprotein levels

Lewis H. Nelson, M.D., Jeanette Bensen, M.S., and Barbara K. Burton, M.D.
Winston-Salem, North Carolina

In a study group of 166 patients with unusually high maternal serum α-fetoprotein values ≥5 multiples of the median, 110 (66%) patients had a condition affecting obstetric care compared with 14% in the 2.5 to 2.9 range, 26% in the 3.0 to 3.9 range, and 30% in the 4 to 4.9 range of multiples of the median. Fetal anomalies composed a significantly greater proportion ($p < 0.0001$) of positive findings in the study group than the group with maternal serum α-fetoprotein values of ≥2.5 to 4.9 multiples of the median. Fetal death either before 20 weeks or of one twin occurred significantly more often in the study group ($p < 0.0001$). Neural tube defects (21%) and fetal death before 20 weeks (19%) were the most common findings in the study group. There was not a statistically significant difference ($p < 0.53$) in pregnancy complications or in late complications between the two groups although oligohydramnios and abdominal pregnancies occurred more often in the study group ($p < 0.029$ and < 0.011). Diagnosticians evaluating patients with unusually elevated maternal serum α-fetoprotein values must be aware of the usual differential diagnosis as well as rarer causes. One must recognize that finding an unaffected fetus does not preclude the subsequent development of a pregnancy complication. (Am J Obstet Gynecol 1987;157:572-6.)

Key words: α-Fetoprotein, ultrasound

Screening programs using maternal serum α-fetoprotein levels have been described in several reports.[1-3] As experience increases, subgroups of patients will be identified, for example, patients with low maternal serum α-fetoprotein values,[4] in whom there is a greater risk of findings that could impact on obstetric care. The purpose of this article is to present outcomes in a group of patients with unusually high maternal serum α-fetoprotein values.

Method

The procedures followed in this screening program have been described.[1] An elevated maternal serum α-fetoprotein value was defined as ≥2.5 multiples of the median and was adjusted for maternal weight and diabetes mellitus. Patients in whom a sample of maternal serum α-fetoprotein equaled or exceeded 5 multiples of the median were identified and monitored for outcome. This subgroup was selected by determining the lowest multiple of the median above which 50% or more of the population had a positive finding. A positive finding was defined as any diagnosis that could adversely affect pregnancy outcome. For analysis and discussion, the results were grouped into the following categories: (1) fetal anomalies (neural tube defects, gastroschisis, omphalocele, triploidy); (2) fetal death (fetal death before 20 weeks, fetal death of one twin); (3) pregnancy complications (twins, oligohydramnios, abdominal pregnancies, placental hemangioma); and (4) late complications (subsequent obstetric complications and fetal death after 20 weeks). Those conditions more related to the maternal-fetal unit such as fetal distress, toxemia, intrauterine growth impairment, premature labor, abruptio placentae, or premature amniorrhexis were grouped under subsequent obstetric complications. Twins were considered as a positive find-

ing and any obstetric complication affecting twins was omitted from the data unless the condition was a neural tube defect, in which case it was counted. Patients were followed up until completion of pregnancy and the patient and physician were contacted for outcome data. Statistical analysis was by Fisher's exact χ^2 test (one-tailed).

Results

Between July 1978 and September 30, 1986, 46,051 patients were screened and there were 1557 (3.4%) who had a first elevation and for whom follow-up data have been completed. Of these, 166 patients had an unusually high maternal serum α-fetoprotein value. The percentages of positive findings for the lower maternal

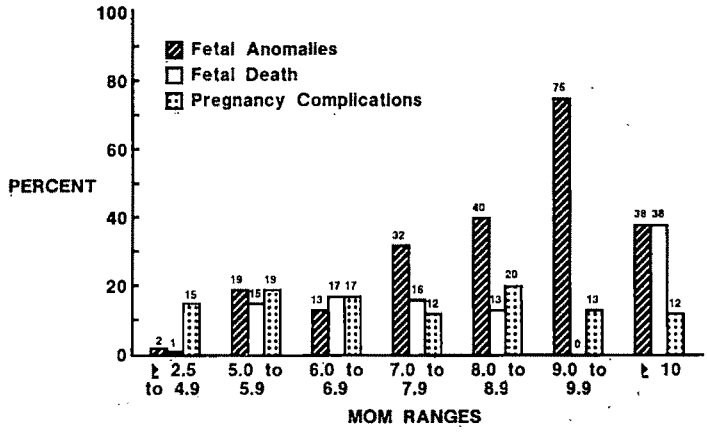

Fig. 1. Distribution of findings. *MOM:* Multiples of the media

serum α-fetoprotein ranges were 14 for 2.5 to 2.9 multiples of the median, 26 for 3.0 to 3.9 multiples of the median, and 30 for 4.0 to 4.9 multiples of the median (Tables I and II). The percentages for the higher maternal serum α-fetoprotein values ranged from 50 to 88. Fetal anomalies composed a significantly greater proportion ($p < 0.0001$) of positive findings in the study group than in the group with maternal serum α-fetoprotein values of ≥2.5 to 4.9 multiples of the median (Table III). Fetal death either before 20 weeks or of one twin occurred significantly more often in the study group ($p < 0.0001$). Neural tube defects and fetal death before 20 weeks were the most common findings in the study group. There was not a statistically significant difference ($p < 0.53$) in pregnancy complications or late complications between the two groups although oligohydramnios and abdominal pregnancies occurred more often in the study group ($p < 0.029$ and < 0.011).

In a subset of the study group defined by an elevation ≥9 multiples of the median, fetal death before 20 weeks and neural tube defects remained the most common findings. The rarer conditions of omphalocele, death of one twin, abdominal pregnancy, and placental hemangioma were all in this subset.

Comment

The cutoff for defining elevated levels of maternal serum α-fetoprotein is usually arbitrarily set at 2.0 to 3.0 multiples of the median for gestational age. Elevated maternal serum α-fetoprotein levels have been associated with numerous adverse outcomes of pregnancy including fetal neural tube defects, spontaneous abortion, stillbirth, prematurity, and intrauterine growth retardation. There is considerable overlap between the distribution of maternal serum α-fetoprotein levels seen in normal pregnancy and those associated with neural tube defects and other anomalies. Many patients defined as having maternal serum α-fetoprotein elevations will have a normal outcome of pregnancy while others will have a benign explanation for the apparent elevation, such as a more advanced gestational age than anticipated or twins. In dealing with unusually high elevations, a benign explanation is rare and one might anticipate an increased frequency of adverse outcomes. Our data (Fig. 1) confirm this by demonstrating a 66% incidence of abnormal findings or adverse outcomes in patients with maternal serum α-fetoprotein elevations ≥5.0 multiples of the median and an 88% incidence in patients with maternal serum α-fetoprotein elevations ≥9.0 multiples of the median. The particularly high frequency in the 9 to 9.9 multiples of the median range is probably the effect of a small total number in that range. Of the 66% with abnormal findings, the majority were fetal anomalies (29%) and fetal death (20%). The significant differences persist for individual findings within fetal anomalies and fetal death. Although pregnancy complications appeared to occur equally in the lower ranges of maternal serum α-fetoprotein elevation and the unusually high values, the individual findings of oligohydramnios and abdominal pregnancies were more frequent in the unusually high groups. Because of the small numbers found in some individual categories, one must use caution in interpreting the data.

Clues to the causes of maternal serum α-fetoprotein values were found by studying the placenta in three of the cases and amniotic fluid volume in six. While triploidy is definitively diagnosed by amniocentesis, a thick placenta may be found at ultrasonography.[10] The other placental abnormality, a hemangioma, was also associated with increased placental mass. Placental abnormalities in patients with elevated maternal serum α-fetoprotein values have been described.[11-13] As placental size increases, the surface area across which α-fetoprotein can pass from fetal to maternal circulation also increases, theoretically resulting in higher ma-

ternal serum α-fetoprotein values. Alternatively, a breakdown in the fetal-maternal/placental barrier may be an explanation.[11] Oligohydramnios has been associated with a poor pregnancy outcome[5, 14] and will be the subject of a later report.

The study group with unusually high maternal serum α-fetoprotein was predestined to have a significant number of conditions affecting the fetus, mother, or both because the group was selected as those in whom more than 50% had significant findings. Identified in this group was a subset, those 44 patients with maternal serum α-fetoprotein values ≥9 multiples of the median, who had an 88% chance of a significant positive finding. This subset requires diligent evaluation by expert ultrasonographers and by amniocentesis.

The two elevations of 13.2 and 19.6 multiples of the median that were associated with abdominal pregnancies deserve special note. There is one previous case report of an elevated maternal serum α-fetoprotein level associated with abdominal pregnancy,[15] making these two the second and third reported cases. One group of investigators found elevated maternal serum α-fetoprotein levels in ectopic pregnancies[16] but noted only two of five values above the ninety-fifth percentile. Considering that the majority of the conditions in this series had significant findings by ultrasound alone, one should be highly suspicious of abdominal pregnancy in a patient with an unusual maternal serum α-fetoprotein elevation and normal ultrasound findings.

This article has presented a summary of pregnancy outcomes in a group of patients with unusually high maternal serum α-fetoprotein levels. Investigation of patients in this group requires thorough knowledge of possible causes, ultrasound, and other diagnostic procedures. One must recognize that finding an unaffected fetus does not preclude the subsequent development of a pregnancy complication.

We wish to acknowledge the assistance of Ms. Chris Morris in maintaining data on the serum α-fetoprotein screening program and diligently researching information for this report.

Discussion

DR. GUY M. MEARES, JR., Columbia, South Carolina (Official Guest). I would like to commend Dr. Nelson and his associates for the information they have presented in this article.

The large and extensive screening experience is readily apparent by the sheer volume of patients who have been screened during this ongoing study.

In their group of 166 patients with >5 multiples of the median, the occurrence of abnormal outcomes in 110 patients depicts high-risk factors for this group. While the incidence of abnormalities in this group is high, the proportion of patients in this group is small relative to the total group screened.

A major problem with maternal serum α-fetoprotein screening is the elevated α-fetoprotein value that is confirmed when repeated and no abnormality can be detected after ultrasound and amniocentesis have been performed. The parental anxiety that is created in this situation may be extremely intense and may mar the couple for the remainder of the pregnancy. While the couple may be reassured from the standpoint of an anomaly, can this elevated value be serving as a warning for the advent of complications later in pregnancy?

Even more important in dealing with the anxiety as-

sociated with α-fetoprotein testing, it is incumbent on us to have timely and qualified ultrasonography and amniocentesis available when elevated α-fetoprotein levels are confirmed. I have been impressed with the number of patients who refuse to proceed with any evaluation after an elevated maternal serum α-fetoprotein level. These same individuals were completely informed of the nature of the testing before its being performed and understood what abnormalities could be present.

I agree that caution should be exercised in predicting risk percentages in groups with small numbers, as with the >9 multiples of the median group.

There are three questions I would like to pose to Dr. Nelson: (1) Why do anomalies compose a greater percentage of the study group when compared with the control group? (2) What is the mechanism of elevated α-fetoprotein levels in fetal death in utero and why does α-fetoprotein rise before fetal death? (3) What is the mechanism of elevated α-fetoprotein levels with oligohydramnios?

Discusser No. 2. I just wanted to correct a misconception about the position of the American College of Obstetricians and Gynecologists in this regard. We opposed the release of the α-fetoprotein testing kits but in spite of our good advice the Food and Drug Administration chose to release them. So the position of the College was that the fellows should be cautioned as to their liability regarding these released testing kits. There would be in the range of a couple of thousand neural tube defects and if one of these babies was born and the patient had not been advised that a test was available, the liability situation would be considerable. It was a caution based on the liability rather than the science.

Dr. Henry A. Thiede, Rochester, New York. Dr. Nelson, I recognize that you have addressed the high values, but I wonder whether you have run across any patients with extraordinarily low values in that large series who subsequently developed choriocarcinoma. Malonski and Ishaguria have indicated that there may be some cause for concern in this group of patients that, even though a fetus is present, they may subsequently be at risk for choriocarcinoma.

Dr. Nelson (Closing). Dr. Thiede, we have not had patients with high values who subsequently developed choriocarcinoma. We are experienced with the ultrasound aspect of low α-fetoprotein values (in press in the *Journal of Ultrascund in Medicine*) but we have not had that experience. To respond to Dr. Meares' questions, a high rate of abnormalities in our study group was predestined by the method by which we selected the study group. We selected a group above which 50% would have some anomalous condition. The issue of maternal serum α-fetoprotein associated with fetal deaths is interesting. Fetal death can be found both in the low group and in the elevated group. I speculate that when the baby dies, whatever the mechanism is that produces the α-fetoprotein ceases and the α-fetoprotein then decreases. As the baby becomes macerated and the skin barrier breaks down, the ability of the α-fetoprotein within the infant to diffuse into the amniotic fluid and then into the maternal circulation increases, resulting in higher levels. This question, however, was more to the point of why does it rise before fetal death? The rise may be related to an event that we are unable to detect and that produces death later on. It is not the death per se that causes the rise but the event that is going to cause the death. We cannot answer that question despite Dr. Pitkin's presentation yesterday. In oligohydramnios, why is α-fetoprotein elevated? I think it is simply a principle of diffusion. The relative α-fetoprotein levels around 16 weeks are about 2,720,000 ng in the fetus and 47 ng in the mother. Therefore I think that a higher concentration per milliliter of amniotic fluid in the infant results in a higher value in the maternal serum.

Mechanical intestinal obstruction in patients with gynecologic disease: A review of 368 patients

Hans-B. Krebs, M.D., and Dean R. Goplerud, M.D.
Richmond, Virginia

To review the management of intestinal obstruction associated with gynecologic disease, the authors studied the records of 368 patients with acute intestinal obstruction. Most patients (83%) had gynecologic malignancies. Obstruction of the small intestines was more common than obstruction of the large intestines (77% versus 23%). Major causes of mechanical small bowel obstruction included extrinsic neoplasms (62%, mostly ovarian carcinomas), radiation therapy–associated strictures and adhesions (17%), postoperative adhesions (14%), and inflammatory strictures and adhesions (3%). Obstruction of the colon was caused mainly by extrinsic neoplasms (45%), strictures and adhesions associated with radiation therapy (26%), fecal impaction (9%), and intrinsic neoplasms (8%). Gastrointestinal intubation successfully relieved 81% of small bowel obstructions caused by postoperative adhesions. Tube suction alone was rarely successful when the obstruction was caused by malignant neoplasms. The prognosis was dependent on the cause of the underlying disease. The cases studied in this report were compared with a large number of cases of bowel obstruction in general surgery. It is concluded that bowel obstruction associated with gynecologic disease has unique features deserving wider recognition. (AM J OBSTET GYNECOL 1987;157:577-83.)

Key words: Mechanical intestinal obstruction, intestinal obstruction in gynecology, bowel obstruction associated with gynecologic disease, obstruction of intestines in gynecology

Although there are several reports of intestinal obstruction associated with ovarian carcinoma,[1-3] comprehensive studies of bowel involvement with diseases of the genital tract are lacking. Therefore, gynecologists must refer to the general surgical literature for guidance if they encounter blockage of the small or large intestines from causes other than ovarian carcinoma. Yet, involvement of the intestinal tract by pelvic disease or gynecologic operations is frequent enough to warrant a separate review. This report is based on experience with intestinal obstruction during a 25-year period on the gynecology service of a large teaching hospital.

Patients and methods

The records of 368 patients with acute mechanical intestinal obstructions were reviewed. The patients were hospitalized between 1960 and 1984 at the Medical College of Virginia. The age of the patients ranged from 26 to 93 years; the mean age was 52.6 years. The diagnosis of obstruction was based on history, physical examinations, and supine and upright roentgenographic films of the abdomen showing dilated loops of the bowel or air-fluid interfaces or both. In 27% of all cases, roentgenographic contrast studies of the small or large intestines, or both, were performed. The clinical diagnosis of intestinal obstruction was confirmed by exploratory laparotomy (with or without intestinal operation) or diagnostic roentgenographic studies, or both, or by autopsy.

Patients with terminal illness receiving supportive care and those with postoperative paralytic ileus were excluded from this study. Cases of incomplete obstruction of the small bowel or colon were also omitted unless there was radiographic evidence of proximal distention of the bowel. Obstruction of the small intestines and colon at the same time were classified as small bowel obstruction if dilated loops of the small bowel were present and as large bowel obstruction if portions of the colon were dilated.

Resolution of the obstruction was defined as remission of pain, vomiting, and abdominal distention, as well as passage of flatus or stool, for at least 30 days. These patients were able to tolerate oral feedings and were discharged from the hospital without surgical intervention.

Operative death is defined as death from any cause within 30 days of the operation. For comparison with a large surgical series, causes of obstruction as a result of gynecologic disease were classified in a manner similar to that described by Wangensteen.[4]

‡All colon carcinoma.

§Radiation therapy 1.2%, pelvic abscess 1.2%.

‖Inadequate end-to-end anastomosis after partial colon resection.

¶Endometriosis.

Results

Incidence of obstruction. During a 25-year period from 1960 to 1984, a total of 368 patients were hospitalized for acute mechanical intestinal obstruction. Forty-six patients (12.5%) had more than one episode of obstruction and were hospitalized two to four times (mean 2.4 times). The 368 patients with intestinal obstruction constitute 1.1% of all patients hospitalized for gynecologic disease. Three hundred five patients (82.9%) had gynecologic cancer or a history of treatment for gynecologic cancer and account for 3.3% of all patients in the oncology section of the gynecology service. Sixty-three patients (17.1%) had benign gynecologic disease accounting for 0.2% of all patients admitted to the benign gynecology section of the gynecology service.

Obstruction of the small intestines was more common than obstruction of the large intestines (283 cases, 76.9% versus 85 cases, 23.1%).

Cause of obstruction. Common causes of obstruction of the small and large bowel are shown in Tables I and II. In Tables I and II the incidence of various causes of obstruction found in patients hospitalized in the gynecology service of the Medical College of Virginia during the study period is compared with the causes of obstruction in a large series of patients in a general surgical ward.[5]

Large bowel obstructions among patients with gynecologic disorders were mostly caused by extrinsic compression from ovarian carcinoma (Table II). An intrinsic process (colon carcinoma) was the single most common cause of large bowel obstruction on a general surgical ward but was also the cause of bowel obstruction of seven patients included in the present series.

These patients developed obstruction of the large bowel while undergoing chemotherapy for presumed ovarian carcinoma. The intrinsic growth pattern of the colonic lesions and identical histologic appearance of the ovarian and colon tumors suggest that in five cases the ovarian malignancies were metastases from previously unrecognized colon carcinomas. In two cases, histologic examination of the ovarian and colon masses showed differences in appearance. It is likely that these patients had two separate cancers at the same time. Only one of the seven patients underwent a barium enema during the original workup of the pelvic masses that, in retrospect, showed a defect in the ascending colon. The lesion was misinterpreted as a "spastic stricture."

Management of obstruction by gastrointestinal intubation. The 283 patients with obstruction of the small intestines developed 339 episodes of obstruction requiring separate hospital admissions. In 303 instances, nasogastric tubes or long gastrointestinal tubes (usually Miller-Abbott tubes) were used at the discretion of the attending physician. The results of conservative management with tube suctioning for gastrointestinal decompression are shown in Table III.

In 76 patients (22.4% of all obstructive episodes; 25.1% of patients with gastrointestinal intubation) the obstruction was successfully relieved by tube suctioning, and surgery was avoided. In 122 instances (40.3% of all cases with tube suctioning) patients responded favorably to gastrointestinal intubation, according to clinical and radiographic evidence. However, the patients were unable to tolerate oral feedings (80 obstructive episodes) or were subjected to surgery without the challenge of oral feedings (42 obstructive episodes). The latter group consisted mainly of patients who were previously treated conservatively for bowel obstruction or for whom surgery was required for conditions such as bulky neoplasms, hernias, or endometriosis.

In 105 instances (34.6% of all patients subjected to tube suctioning) gastrointestinal intubation did not result in clinical or radiographic improvement. All 227 patients with obstructions not relieved by tube suctioning were treated surgically. Thirty-six additional patients underwent surgery within 6 hours after the diagnosis of small bowel obstruction was made, without having undergone a trial of intestinal decompression with tube suctioning.

Seventy-seven patients with colon obstruction not caused by fecal impaction had 80 instances of obstruction. Gastrointestinal intubation was used during 60 of these obstructive episodes (75%) in preparation for surgery. The eight patients with fecal impaction were treated conservatively by enemas or ingestion of laxatives and mineral oil.

Management of obstruction by surgery. In the 263 episodes of small bowel obstruction managed by exploratory laparotomy, corrective surgery consisting of lysis of adhesions, resection of tumor compressing the bowel, or resection of the obstructed bowel segment and reanastomosis of the free bowel ends was possible

in 189 cases (71.9% of all operations). In 50 cases (19%) the obstructive bowel segment was bypassed and a portion of the bypassed bowel was exteriorized as a mucous fistula proximal to the obstruction. In 24 (9.1%) of the patients who underwent exploration, corrective surgical treatment could not be carried out because of carcinomatosis.

Surgery was performed in all 80 cases of large bowel obstruction not caused by fecal impaction. Primary resection of the obstructing lesions or the obstructed bowel segment, with or without reanastomosis of the colon, was possible in 43 cases. In 24 of the 43 cases the proximal colon was decompressed by a (usually transverse) colostomy, which was reversed at a later time in 16 cases. In 19 cases the obstruction was relieved without the need for colostomy. In 37 obstructive episodes, fecal diversion was carried out by means of colostomy (32 cases), ileostomy (four cases), and cecostomy (one case). The obstructing lesion or the obstructed colon segment was resected and bowel continuity reestablished later in 16 (43.2%) of these patients.

Deaths. Patients who were successfully treated for small bowel obstruction by tube suctioning alone had mostly postoperative adhesions or adhesions related to radiation therapy. In the absence of active cancer, none of these patients died of sequelae related to bowel obstruction.

The prognosis of surgically treated small bowel obstruction depended on the underlying cause of the obstruction. The mortality rate was the highest for patients with malignant neoplasms and radiation damage of the bowel (inflammatory strictures and adhesions) (Table IV). Twenty-four patients whose obstruction could not be relieved surgically died of complications related to the persistent obstruction. Four patients with presumed surgical relief of the obstruction had persistent obstruction or developed recurrent obstruction leading to death within 30 days of the surgery. Other causes of postoperative death include peritonitis (10 cases), sepsis (four cases), pulmonary embolus (three cases), cerebrovascular accident (two cases), myocardial infarction (two cases), and pneumonia (one case).

Eight patients with obstruction of the large intestines suffered fatal complications (Table IV). Their deaths were caused by peritonitis (three cases), sepsis (two cases), persistent obstruction as a result of carcinomatosis (two cases), and pulmonary embolism (one case).

Comment

Incidence of obstruction. Obstruction of the large and small intestines in gynecology is most commonly (83%) associated with pelvic neoplasms, most notably ovarian carcinoma. Almost 50% of the patients who die of ovarian cancer can be expected to develop small bowel obstruction during the illness.[6] More than 3% of patients on the gynecologic oncology service of the Medical College of Virginia had bowel obstruction. By contrast, patients admitted for benign gynecologic disease had bowel obstruction in 0.2% of the cases. Obstruction of the small intestines was more common than obstruction of the large intestines (77% versus 23%).

Causes of obstruction. The most common causes of small bowel obstruction associated with gynecologic disease were extrinsic compression from ovarian carcinoma, postoperative adhesions and inflammatory strictures, and adhesions secondary to radiation therapy. By contrast, patients on a general surgical ward were more likely to have postoperative adhesions and external hernias causing obstruction of the small intestines. More than 20% of all small bowel obstructions caused by adhesions result from gynecologic surgery.[7]

Obstruction of the large bowel in patients with gynecologic disorders was caused mostly by extrinsic compression from ovarian carcinomas, inflammatory strictures secondary to radiation therapy, and fecal impaction. Although much more common on a general surgery ward, colon carcinoma was responsible for large bowel obstruction in seven patients in this series who were treated for ovarian carcinoma. This fact underscores the need for careful evaluation of the large bowel by testing for occult blood and performing appropriate endoscopic or roentgenographic studies in patients thought to have ovarian carcinoma. Thorough intraoperative palpation of the entire large bowel should always be part of an abdominal exploration.

Management of obstruction by gastrointestinal intubation. Gastrointestinal intubation is highly effective for treating small bowel obstruction caused by postoperative adhesions. The success rate of 81% in the present series is similar to those reported by other authors.[8,9] Partial small bowel obstruction is more likely to respond to tube suctioning than is complete obstruction.[8-10] Obstruction occurring <30 days after surgery has a better prognosis than obstruction occurring >30 days after surgery.[9] More than 70% of all small bowel obstructions caused by adhesions will respond to intestinal suctioning within 24 hours.[10]

Tube suctioning is rarely successful when the obstruction is caused by neoplasms or strictures associated with radiation. Patients who do respond to gastrointestinal intubation may be managed temporarily by dietary modifications consisting of a low-residue diet or dietary supplements with little or no residue. However, the anatomic defect tends to worsen, and surgery eventually becomes necessary in nearly all patients.[6] Only occasionally will a patient with bowel obstruction secondary to ovarian cancer respond to chemotherapy and have long-lasting benefits from conservative management.[11]

Traditionally, long gastrointestinal tubes such as the Miller-Abbott tube, Baker tube, or Cantor tube were employed whenever possible to achieve maximum decompression of the distended bowel proximal to the obstruction. Although occasionally time-consuming and laborious, passage of long tubes into the small bowel can be achieved in one attempt in 70% of patients with obstruction as long as bowel peristalsis is present.[8] Brolin[10] recently suggested that partial small bowel obstruction may be treated more efficiently with a nasogastric tube instead of a long tube. In cases of complete small bowel obstruction requiring surgical intervention the advantages of a long tube outweigh its disadvantages. Particularly in cases of obstruction caused by adhesions, intraoperative advancement of a long tube through the entire bowel serves to "splint" the intestinal loops and may prevent recurrence of the obstruction. In addition, intestinal distention may be relieved by suctioning bowel contents intermittently while the tube is being advanced intraoperatively. Although this maneuver facilitates closure of the abdomen, it may also retard resumption of bowel activity.[12]

Treatment of large bowel obstruction is primarily surgical, and decompression of a severely distended colon is achieved by temporary colostomy of the transverse colon. Gastrointestinal intubation for removal of swallowed air and succus entericus may still be of value while the patient is being prepared for surgery. Unless there is distention of the small bowel as a result of incompetence of the ileocecal valve, use of a nasogastric tube appears to be appropriate.

Management of obstruction by surgery. Although early surgical intervention within 12 to 24 hours after diagnosis of the obstruction has been advocated,[7, 13] the more recent surgical literature suggests that an expectant behavior of up to 48 hours and even longer appears justified as long as serial x-ray films and clinical evaluation indicate improvement of the intestinal distention.[6, 10] Lack of improvement or worsening of the clinical and radiographic findings beyond 12 to 24 hours indicates a high complication rate and poor prognosis.[5, 6, 14]

The surgical treatment of small bowel obstruction is dictated by the underlying cause of the problem. Whereas lysis of adhesions and splinting of the small bowel is appropriate for treating obstruction caused by adhesions, obstruction caused by tumors and strictures is best managed by resection of the obstructed bowel segment and reanastomosis of the free bowel ends. In 19% of the patients in the current study, this approach was not feasible because of extensive tumors. The obstructed bowel segment is then bypassed and a suitable portion of the bypassed bowel is exteriorized as a mucous fistula proximal to the obstruction. In some 9% of the patients the entire small bowel may be encased by tumor or may form a conglomerate with the tumor so that surgical relief of the obstruction is not possible.

Treatment of large bowel obstruction by primary resection is feasible when the degree of intestinal distention is not severe. In almost half of the patients studied, severe distention of the colon required a fecal diversion by colostomy, ileostomy, or cecostomy. Advanced cancer or changes associated with radiation prevented bowel continuity from being reestablished in most cases.

Operative deaths. The operative mortality rate of bowel obstruction associated with gynecologic disease is high and reflects the underlying cause of the disease. Most patients who died during the postoperative period had advanced ovarian carcinoma. The prognosis of these patients is quite unpredictable by comprehensive assessment of risk factors.[3] The prognosis is poor for patients with rapidly reaccumulating ascites, advanced age, severe nutritional deprivation, liver metastases, or distant metastases or those who have responded poorly to combination chemotherapy or total abdominal radiation therapy.[3]

Discussion

Dr. James L. Purcell, Charleston, South Carolina (Official Guest). This is an excellent review of 368 gynecologic patients with intestinal obstruction at the Medical College of Virginia between 1961 and 1984. Drs. Krebs and Goplerud's primary goal was to establish and clarify guidelines for gynecologic surgeons in the management of intestinal obstruction. They also contrasted etiologic differences of intestinal obstruction in the general surgery and gynecologic services. They indicated that it is the cause of the obstruction in the gynecologic patient that can be used as one of the primary tools in determining the sequence and modality of management, as well as predicting postoperative morbidity and mortality rates.

In this review intestinal obstruction accounted for only 1.17% of the gynecologic admissions. Although the incidence is not extremely high, this is a very dramatic complication for both the patient and her physician.

It is of interest that 83% of the patients had some type of gynecologic malignancy as the cause of obstruction. The vast majority of patients had ovarian carcinoma. Dr. Krebs stated that 50% of the patients who die of ovarian carcinoma have an intestinal obstruction some time during the course of the disease. The remaining 17% are most likely to be of concern to the primary gynecologist. These include radiation, strictures and adhesions, postoperative adhesions, and inflammatory strictures and adhesions.

Small bowel obstructions were far more common than those of the large bowel: 77% and 23%, respectively. These figures compare favorably with those of other teaching institutions.

Three hundred three of 339 episodes of small bowel obstructions were treated initially with gastrointestinal intubation. As other authors have confirmed, this is highly effective for small bowel obstruction secondary to postoperative adhesions. In this review small bowel obstructions that occurred within 30 days of the primary surgery had a better prognosis than those that occurred after 30 days. The small bowel obstructions secondary to malignancy or radiation were rarely totally responsive to gastrointestinal intubation. Large bowel obstruction virtually never responded to intubation even with the long tube. Their review also indicated that if an obstruction is going to resolve with intubation it will do so within 24 hours. The older literature dictated that morbidity and mortality rates increased with expectant management after 24 hours. However, Krebs and Goplerud's review indicated that as long as there was clinical and radiologic improvement, the risk did not increase with expectant management up to 48 hours or longer, although with failure to improve or deterioration of the patient's condition, surgical intervention was indicated.

The surgical management of small bowel obstructions constituted lysis of adhesions if indicated. If the obstruction was secondary to malignancy, resection of the involved bowel and tumor or bypass procedures produced the best result. In 9% of the obstructions in this review the small bowel was totally encased with tumors and resection was impossible.

The 80 large bowel obstructions were surgically treated by primary resection with or without reanastomosis or colostomy and resection at a later date. It was of interest that five of the larger bowel obstructions were primarily felt to be secondary to ovarian malignancy but at surgery were found to be primary colon carcinoma with metastasis to the ovary. Two patients had double primary lesions of the colon and ovary. Drs. Krebs and Goplerud stressed that the bowel must be thoroughly inspected for other malignancies at the time of surgery.

Drs. Krebs and Goplerud suggested in this review that one of the long gastrointestinal suction tubes should be used in all cases of complete obstruction where decompression is needed. This is in contrast to some articles in the current literature and my discussion of the matter with other gynecologic oncologists. Their opinion was that the nasogastric tube was adequate for intestinal obstruction secondary to postoperative adhesions or inflammatory adhesions. Obstruction secondary to radiation or malignancy may respond to a nasogastric tube, but if not, a long tube may be substituted.

I feel that Drs. Krebs and Goplerud have accomplished their goals in this review by giving us a better insight into intestinal obstruction as it relates to gynecologic disease. Their comparison of the etiologic factors and their prognostic value for gynecologic intestinal obstruction and general surgical intestinal obstruction were helpful. The care of most gynecologic malignancies is referred to oncologists today and therefore they see the vast majority of intestinal obstructions.

In a paper Dr. Krebs presented at this meeting last year, he made a plea for better training in gastrointestinal surgery for our residents. I concur with this in every respect. However, with the cloud of litigation hanging over our heads, the private gynecologists may save himself questions later if he obtains a surgical consultation to assist in the management of bowel obstruction. I would like to hear Dr. Krebs' feelings about this aspect of the management of bowel obstruction.

Dr. Thomas K. Young, Gainesville, Florida. I cannot help but think that the majority of benign or obstructive complications secondary to adhesions would end up in general surgical literature. I wonder if Drs. Krebs and Goplerud have some information as to what percent of adhesive obstruction in general surgical series is related to initial gynecologic surgery.

Dr. Matthew Burrell, Atlanta, Georgia. I would like to know whether bypass or resection was used in the group who underwent irradiation. There is information to suggest that resection carries a higher morbidity rate.

Dr. Krebs (Closing). Dr. Purcell made a comment regarding the use of long tubes in all cases. I think the way the article should have read is that the long tube was used in the majority of the cases. There were certainly patients there who were treated with nasogastric suction. Our prime cause for using the nasogastric suction tube placed into the stomach would be in patients in whom there are no bowel sounds or function evident on ascultation. In those cases you cannot expect that a long tube will be transported to where it is needed. In the stomach a long tube is not as effective as the standard nasogastric tubes. A second point would be in regard to the management of the patients who have bowel problems related to general gynecologic problems. The figures that I showed you indicate quite clearly that the general gynecologist is not going to encounter many cases of bowel obstruction associated with the diseases he treats. Nor is he generally capable of handling relatively complicated procedures related to bowel obstruction, which brings me to the comment that those patients will probably be operated on in association with a gynecologic oncologist or would simply be referred to a general surgeon. The final comment on bypass versus resection is an issue that is still being debated by gynecologic oncologists. I prefer resection of the lesion if this can be done with reasonable effort. In many of the patients the effort is unreasonable and it is a much simpler procedure to bypass the obstructed, usually heavily irradiated bowel that is stuck together deep in the pelvis. However, we have noticed that the outcome has been quite favorable in those patients in whom a bowel resection in a radiated patient was attempted and carried out. Once again it lies somewhat in the individual's judgment and his surgical experience which of the two methods of surgery he chooses.

Fetal death: Diagnosis and management

Roy M. Pitkin, M.D.
Iowa City, Iowa

Death of the fetus after 20 weeks of gestation complicates about 1% of pregnancies. Of various means of diagnosing fetal life and death, real-time ultrasound visualization of the fetal heart is the most accurate. Delivery of the dead fetus can be effected by various means, but in most instances, at least before 28 weeks and perhaps thereafter as well, the simplest and most effective method is with prostaglandin vaginal tablets. A variety of conditions are known to cause fetal death or increase the risk that it will happen, but these account for only about 50% of cases. Four special tests may identify a cause of the "unexplained stillbirth" in the other 50% of cases. These tests include karyotype, listerial culture, fetomaternal hemorrhage, and lupus anticoagulant. (Am J Obstet Gynecol 1987;157:583-9.)

Key words: Fetus, death, causes, diagnosis, therapeutic options

The death of a fetus is one of the unhappy events in the field of obstetrics. A particularly distressing experience that is encountered all too often is its occurrence utterly without warning in a pregnancy that has previously seemed entirely normal. Though certain diseases and conditions in the mother or the fetus are associated with increased risk, much of the time the cause of fetal death cannot be identified by even the most thorough search, intensifying the sense of frustration felt by both patient and physician.

From the Department of Obstetrics and Gynecology, The University of Iowa.

The definition of fetal death, specifically the stage of gestation encompassed by the definition, differs among various public health authorities, which makes comparison of fetal mortality problematic.[1] The World Health Organization defines fetal death as that occurring before the complete expulsion or extraction from the mother of a product of conception, irrespective of the gestational age. However, the U.S. National Center for Health Statistics uses only deaths at or after 20 weeks of gestation to report vital statistics. To complicate the situation even further, six states (Colorado, Georgia, Hawaii, New York, Rhode Island, and Virginia) require the report of a fetal death at any point of gestation, and at least some of the time they calculate their state rates on the basis of all reported deaths. Finally, certain countries other than the United States, particularly developing nations, calculate fetal mortal-

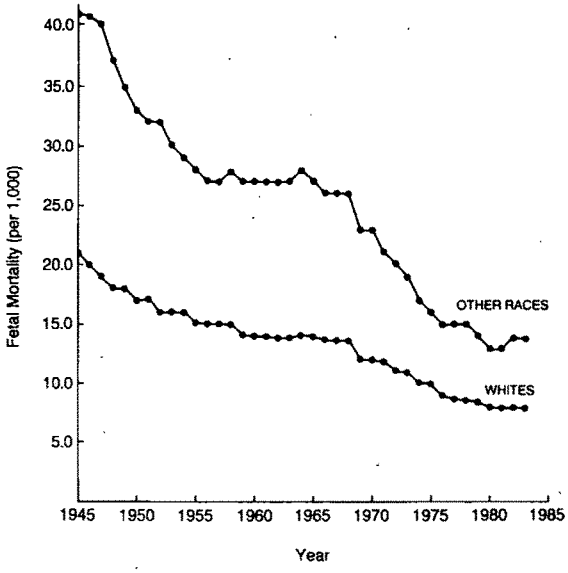

Fig. 1. Fetal mortality reported by National Center for Health Statistics. [Reproduced with permission from *Clinical Obstetrics and Gynecology.* Petitti D. Clin Obstet Gynecol 1987;30:253-8.]

ity on fetal deaths at ≥28 weeks of gestation. Thus, whenever a fetal mortality is mentioned, it is essential to know the definition of fetal death that is used to arrive at the numerator. It is also important to know whether the denominator represents total or live births. Technically, the use of the latter provides a "ratio" rather than a "rate."

Fetal death rates over the last 40 years in the United States are illustrated in Fig. 1. The most striking features is the racial difference, which although it has narrowed progressively, continues to indicate a substantial advantage of whites over numbers of other races. Another features of this illustration of fetal mortality patterns is the relative stability in both races during the decade of the 1960s. Many changes in care practices—family planning, abortion, maternal nutrition, fetal monitoring, and neonatal intensive care, to mention only a few—have been claimed as responsible for the decline in fetal mortality since 1969. However, the complexities of the relationships do not permit estimation of the relative contribution of any of these factors.

Causes

Only relatively infrequently is it possible to identify a specific condition that directly causes death of the fetus. Umbilical cord prolapse and premature separation of the placenta are examples of such direct causes. More often conditions are known by experience to be associated with increased risk of fetal death, though the precise mechanism is obscure. Among these types of associated conditions are various medical complications

Table I. Causes of fetal death

Cause of death	*Percent of deaths*
Hypertensive disease	5-25
Medical complications	5-10
Erythroblastosis fetalis	3-15
Cord and placental complications	10-20
Congenital malformation	5-10
Intrauterine infection	5-15
Unexplained	~50

of pregnancy, notably hypertensive disease and diabetes mellitus. Though many controversies and uncertainties surround the topic of postdatism, there can be little doubt that the risk of fetal death increases as gestation extends beyond 42 weeks.

Table I lists various causes of fetal death, along with an estimate of the proportion of deaths associated with each, drawn from a variety of sources in the literature and from personal experience. Ranges are given, since the proportions vary considerably in different populations. For example, hypertensive disease (usually acute but occasionally chronic) accounts for as few as 10% of fetal deaths in some series but as many as 25% in others, depending on the frequency of the disease in the particular population from which the series is drawn. These data also vary with the era from which they come. For example, erythroblastosis fetalis caused by rhesus factor isoimmunization formerly accounted for 15% to 20% of fetal deaths in some series, but the proportion has declined, both relatively and absolutely, with the advent of rhesus factor immunoprophylaxis. However, it is important to note that the problem of rhesus factor sensitization has not gone away altogether.

The most striking feature of the cause of fetal death is that when all the known and suspected causes and associated conditions are added together, they account for no more than 50% of observed fetal deaths, leaving half or more undiagnosed and presumably undiagnosable as far as causation is concerned. Every physician who practices obstetrics for any period of time has had a distressing experience something like the following: some time during late gestation, a woman who has had an entirely normal pregnancy reports with a certain anxiety in her voice that she has not felt her fetus move for some hours or 1 or 2 days. Auscultation fails to identify a fetal heart beat, and real-time ultrasound confirms the absence of cardiac activity in the fetus.

This scenario, all too familiar to every obstetrician, is distressing to the physician and devastating to the patient. Typically, it prompts a frantic and haphazard search to determine the cause, a search which most of the time proves fruitless as far as any specific findings are concerned.

Autopsy of the stillborn fetus typically consists of a cursory gross examination that leads to a report of "macerated stillborn." Thus, at least as customarily conducted, the autopsy adds little in resolving concerns about causation. However, a careful and meticulous examination by an individual experienced and skilled in perinatal pathology can illuminate a substantial proportion of the ≥50% of cases for which no cause is otherwise apparent.[2,3] If an autopsy is not to be done, a full-body radiograph of the fetus can identify skeletal abnormalities.

Diagnosis

Suggestive signs of fetal death, specifically the woman's inability to perceive fetal movements and the physician's inability to hear the fetal heart beat, are imprecise at best. Before acting it is necessary to establish the diagnosis with absolute certainty, something that is rarely easy.

Radiography. For more than 50 years, radiography was the principal means of confirming the diagnosis of fetal death. The most reliable sign, the presence of gas in the fetal vasculature (Fig. 2), is also a useful test, since it can appear within 1 or 2 days of death. Its principal disadvantage lies in its low sensitivity; no more than half of fetal deaths are accompanied by this sign.

Other radiographic signs reflect one or another manifestation of fetal maceration and are less specific. Moreover, these are of less use clinically because of the time required (10 to 14 days) for their development. Overlapping cranial sutures, known as Spalding's sign, develop eventually in nearly all cases but may be mimicked by the normal molding process that accompanies labor. Abnormal angulation of the fetal spine as a result of collapse of the vertebral bodies, a quantitative change, is sometimes difficult to recognize.

Ultrasound. Ultrasound imaging of fetal cardiac activity has, over the past decade, become the most useful diagnostic test in cases of suspected intrauterine death. A-mode or time-motion ultrasonography may be used, but the simplest and most useful technique is that which uses real-time equipment. Heart wall motion and valvular function can be visualized readily, and failure to detect this activity after 10 to 12 menstrual weeks of gestation constitutes reliable evidence of fetal death.[4] However, the ultrasound diagnosis of fetal death is somewhat more difficult than that of fetal life; it should be confirmed by two independent observers, each taking a minimum of 3 minutes of study.[5]

Though real-time ultrasound has become the "gold standard" for antenatal diagnosis of fetal life or death, it should be remembered that this technique has a subjective component that makes it liable to observer error. In one case at the University of Iowa, a woman suspected of having intrauterine fetal death was examined by an experienced sonographer who confirmed the diagnosis, only to deliver a living infant several days later.

Fig. 2. Abdominal radiograph taken 2 to 3 days after fetal death in late pregnancy. *Arrows* indicate gas in fetal aorta and/or vena cava.

Other ultrasound findings with fetal death include scalp edema and other maceration sequelae that can be visualized radiographically. Occasionally, these adjunctive findings are useful.

Amniotic fluid and hormones. The amniotic usually becomes discolored at about the same time the fetus dies. Most often it is a deep mahogany-red shade, the so-called "tobacco juice" appearance that apparently results from hemoglobin products or the thick brown "pea soup" that characteristically reflects the passage of meconium. However, these changes are neither entirely sensitive nor entirely specific and should be regarded as adjunctive or confirmatory signs. The volume of amniotic fluid is often diminished in cases of fetal death, but whether this precedes or follows the event is unknown.

The concentration of the enzyme creatine kinase in amniotic fluid increases rapidly with fetal death, from <3 σ U/ml in normal circumstances to >5 σ U/ml 24 to 48 hours after death.[6] This test may have some use in occasional instances.

Among the various pregnancy hormones, estriol is

the most useful index of fetal health or disease. Levels in either blood or urine decrease dramatically 24 to 48 hours after fetal death, a finding that can be useful diagnostically. Progesterone is less helpful because, as a hormone entirely of placental origin, production may be maintained for variable times after the fetus dies. Chorionic gonadotropin levels may have some value in assessing early pregnancy complications, including embryonic and fetal death. α-Fetoprotein levels in maternal serum and amniotic fluid are elevated with fetal death, but the finding is not specific enough for use in diagnosis.

Management

Once the diagnosis of fetal death is established, the proper management needs to be decided on. However, some appreciation of the natural history is essential in evaluating the therapeutic options. At least 75% of women labor spontaneously within 2 weeks of fetal death, and most of the others will have delivered by the time another 2 weeks have elapsed. However, some variation in this timetable exists with respect to the timing and the cause of fetal death. As a general rule, the interval between death and spontaneous labor varies inversely with the stage of gestation at which the fetus dies. In other words, the earlier in pregnancy the death occurs, the longer the period of latency until the fetus is expelled. Moreover, certain causative conditions seem to be associated with longer latency periods than others for reasons that are not altogether clear. A case in point is erythroblastosis fetalis, which is well-known to predispose to prolonged retention of the dead fetus.

The development of a coagulopathy associated with the dead fetus syndrome was first recognized >30 years ago. Initially thought to result from erythroblastosis fetalis (a misconception that can be understood in view of the commonness of rhesus factor isoimmunization in that era and the tendency for prolonged retention of the fetus that died from erythroblastosis), it is now recognized as a potential complication of fetal death from any cause. The pathophysiology involves release of thromboplastic substances from the products of conception into the maternal circulation, promoting disseminated intravascular coagulation that gradually consumes the maternal clotting factors, particularly fibrinogen and platelets.

Development of the consumptive coagulopathy that accompanies fetal death is a gradual process, in contrast to that accompanying abruptio placentae or amniotic fluid embolus. Laboratory evidence does not appear until 3 or 4 weeks after the fetus dies, and thereafter the serum fibrinogen level and/or platelet count decrease progressively but slowly; the rate of decline in fibrinogen level has been quantitated at 20 to 85 mg/dl/week.[7] Thus clinical hemostasis is maintained for some time. In expectant management of a woman who has sustained fetal death, it is not necessary to measure coagulation indices until several weeks have elapsed, and then a sampling interval of once weekly generally provides adequate monitoring. Hemorrhage from coagulopathy will not occur until the coagulation indices reach critical levels, such as a serum fibrinogen value <100 mg/dl and a platelet count <50,000/mm^3, which rarely if ever occurs before 6 weeks from the time of death. Sampling once or twice weekly is ample to identify those patients who need intervention (i.e., delivery) before hemorrhage becomes a threat.

Therapeutic options. At least five options are available to the clinician caring for a woman whose fetus has died: (1) expectancy; (2) mechanical evacuation through the cervix; (3) intravenous administration of oxytocin; (4) amnioinfusion with hypertonic solution; (5) prostaglandin administered vaginally, systemically, or intra-amniotically. Each offers both advantages and disadvantages, and none is ideal in every case.

Expectant or conservative management represents a reasonable choice in that spontaneous expulsion will occur eventually in all cases. Moreover, it is safe as long as the maternal coagulation status is monitored as outlined previously and changes approaching the danger zone are acted on by effecting prompt delivery. The disadvantage of the conservative approach lies in its adverse emotional impact. Fetal death, particularly when it occurs unexpectedly but also when risk is known to be high beforehand, is emotionally devastating and the near-universal patient response is an overwhelming desire to have the uterus emptied as soon as possible. The prospect of waiting days and even weeks for spontaneous labor is simply unacceptable to the overwhelming majority of women. Nevertheless, it may be the treatment of choice in the occasional instance in which coexistent medical conditions contraindicate other therapeutic options.

Mechanical dilation of the cervix and evacuation of the uterus by suction or other means is clearly the method of choice when the uterus is small enough to permit safe performance of the operation. What uterine size is regarded as "safe" will vary with the physician's skill and experience with this type of surgery. For most gynecologists, the point at which risk-benefit analysis argues against this approach lies somewhere in the junction between the first and second trimesters (i.e., uterine size of 13 to 14 weeks of gestation). In any case, transcervical evacuation of the missed abortion–dead fetus carries increased risk of bleeding, so the operation should always be approached with caution. Specifically, it should be done in a properly equipped surgical facility (rather than an ordinary clinic), an intravenous infusion must be initiated, and blood should be available.

Oxytocin given in dilute intravenous infusion offers advantages by virtue of its familiarity and relative safety. However, although it typically promotes uterine contractions, its efficacy in effecting delivery may be limited, particularly in cases of fetal death remote from term. Large doses and prolonged administration may be required, circumstances that increase the risk of water intoxication and attendant central nervous system complications. To avoid such very serious sequelae, extreme care to avoid prolonged administration in large volumes of electrolyte-free solutions must be exercised.

Amnioinfusion with a hypertonic solution, most commonly sodium chloride but occasionally glucose or urea, is effective in emptying the uterus. Its principal disadvantage involves the small but definite risk of serious complications. Because of the oligohydramnios that quite regularly accompanies fetal death, amniocentesis can be technically difficult in such cases, and there may be uncertainty as to the exact location of the needle. If the tip of the needle should lie outside the uterine cavity (e.g., in the uterine wall or a maternal blood vessel), rapid infusion of a large volume of hypertonic solution can be fatal. Another risk, at least theoretically, is that of aggravation of any concomitant coagulopathy. For these reasons, amnioinfusion has a limited value in the termination of pregnancies in which the fetus has died.

Prostaglandins (PG) are potent uterine stimulants, and a number of different PG types and formulations have been used in effecting delivery of the dead fetus. The most commonly used approach involves PGE_2, administered intravaginally and available commercially as suppositories containing 20 mg of the active agent. Typically given as one suppository and repeated at 3- to 4-hour intervals until delivery is imminent (usually within 12 hours), this treatment has been demonstrated to be highly effective in a number of studies.[8] Side effects are frequent, nearly all patients exhibit some degree of fever and tachycardia and half or more have vomiting and/or diarrhea, but these typically present only minor problems clinically. Moreover, they may be ameliorated by lowering the dosage (e.g., to half of a suppository), lengthening the interval, and pretreating with medications for the various side effects. An uncertainty about intravaginal PGE_2 involves the product-labeling injunction that it be used only in deaths occurring up to 28 weeks of gestation, presumably reflecting rarely reported serious complications, particularly uterine rupture[9] in later pregnancy. Though several reports have documented safety with third-trimester usage,[10] the matter of the labeling statement makes its use under such circumstances problematic. For example, if a patient is given PGE_2 vaginal tablets in late pregnancy and sustains a complication of any type and for any cause, the responsible physician may be in jeopardy (or at least be in an uncertain situation) in a medicolegal sense. If use in late pregnancy is contemplated, lowering the dose and avoiding concomitant oxytocin use (since this has been employed in the serious complications reported) seem prudent.

Other PG formulations and routes of administration have been used in managing fetal death. Intravenous PGE_2 (0.5 to 2.5 μg/min), intramuscular 15-methyl $PGF_{2\alpha}$ (250 mg every 2 hours), and intra-amniotic $PGE_{2\alpha}$ (40 mg) have all been reported effective in relatively small series.[8] In general, both efficacy and side effects seem similar to those related to the more familiar PGE_2 vaginal suppositories.

Management suggestions. In view of the variety of options available and their advantages and disadvantages, individualization of treatment should be regarded as the cornerstone of management. However, it is possible to set forth certain guidelines.

The instance in which uterine size permits the prospect of reasonably safe cervical dilation and evacuation by instruments and/or suction is straightforward. The risk of hemorrhage is greater than that with interruption of normal pregnancy, and as indicated previously, special precautions in this regard are indicated.

Among cases uncomplicated by other diseases or conditions, fetal death during the second trimester can usually be managed most simply and effectively by PGE_2 vaginal tablets, perhaps with premedication to minimize side effects. When death has occurred during the early third trimester (e.g., between 28 and 34 weeks), amnioinfusion with hypertonic saline solution may be considered if technical conditions (including real-time ultrasound monitoring) provide assurance of safety; intravaginal PGE_2 (in reduced dosages) also represents a viable option if the physician is comfortable with the medicolegal uncertainties involved. With fetal death in the last month or 6 weeks of gestation, intravenously administered oxytocin is probably the best choice; an expectant approach may also be considered, since the period of latency is likely to be short. In all cases, osmotic dilators of the cervix may be useful adjuncts.

The presence of coexisting complications may require some modifications in these gudielines. For example, PG usage in any form is likely to be accompanied by cardiovascular side effects, making these agents at least relatively contraindicated in women with significant cardiovascular or renal disease. Amnioinfusion of hypertonic saline solution should probably also be avoided with these medical complications, and intravenous fluid volume in oxytocin treatment requires careful attention. In view of the tendency to bronchospasm with PGs, these agents should be used with caution in patients who have asthma.

In the rare case in which a coagulopathy has devel-

oped because of neglect, a course of intravenously administered heparin will restore coagulation factor levels to normal before uterine evacuation.[11]

An unusual but potentially serious complication is the death of one fetus of a multifetal gestation. If monozygotic, the surviving fetus or fetuses may be at some risk of thrombotic complications apparently caused by fetal-fetal exchange of thromboplastic material through vascular shunts in the monochorionic placenta.

Searching for the cause

The occurrence of an unexplained fetal death (i.e., one that happens unexpectedly and is unaccompanied by any apparent cause or associated conditions) prompts an immediate and often somewhat disorganized search for the cause. Typically, the history is gone over in detail, the syphilis serology is repeated, the blood pressure and kidney function are assessed, antibodies to a variety of viruses and other infections are measured in the woman's blood, and a perfunctory autopsy is performed. These results usually fail to reveal anything of significance. The patient is told that she is in that 50% of situations in which there is no known cause, and she is given variable (and sometimes impenetrable) advice about the prognosis in a subsequent pregnancy.

This investigative protocol has become ritualized, and as with any ritual, it has lost any original meaning. However, several "special tests," some new and others not so new, exist, which offer a much higher yield in identifying the cause of a fetal death. Four tests will be discussed briefly: (1) karyotype, (2) listeriosis, (3) fetomaternal hemorrhage, and (4) lupus anticoagulant.

Karyotype. Some 5% to 6% of stillbirths demonstrate some type of chromosomal abnormality,[12] an incidence 10 times that in live births. As a general rule, the earlier in gestation that fetal death occurs, the larger the proportion of chromosomal anomalies. By far the most common karyotypic abnormality is trisomy. Among 2517 spontaneous abortions and fetal deaths up to 28 weeks studied by Warburton et al.,[13] 55% of the abnormal karyotypes were trisomies (most commonly trisomy 16, which never occurs in live births, followed by 21, 22, 13, 15, and 2). The remaining abnormal cases included monosomy X (18%), triploidy (15%), and tetraploidy (6%).

Although karyotyping has a relatively high yield when applied in all cases of fetal death, the substantial cost of chromosome culture makes some selectivity advisable. Among findings associated with chromosomal abnormalities, which therefore can be expected to increase the yield, are (1) physical stigmas that suggest a single gene disorder, (2) multiple anomalies, (3) fetal growth retardation, (4) Potter's syndrome, and (5) nonimmune hydrops.

The success of chromosome culture varies inversely with the time between death and delivery. Nevertheless, the success rate is still reasonable, even when substantial autolysis has taken place, so the study should be used in any case in which it seems to have potential value. The diaphragm is the best tissue to culture, and in cases in which amniocentesis is possible, amniotic fluid cells may be used.

Listeriosis. *Listeria monocytogenes* is a gram-variable rod that causes mild and often asymptomatic infection in the adult but a much more serious condition in the fetus. The principal route is believed to be transplacental from maternal septicemia, leading to an abscess formation in the placenta and then to fetal septicemia. More rarely, infection may occur by an ascending route to cause chorioamnionitis.

Several outbreaks of listeriosis have occurred in recent years, principally from ingesting contaminated foods, especially cheese and other dairy products. Reports of these have included a number of perinatal deaths caused by infection of pregnant women, implying that the fetus is at special risk.[14, 15] The magnitude of any risk is unknown, since no data on listeriosis in nonfetal cases exist.

Because fetal listeriosis can occur with little in the way of maternal illness (at most, a mild and nonspecific influenza-like syndrome), the possibility should be considered in otherwise unexplained stillbirth. The organism grows relatively slowly in culture and may be missed unless sought specifically. Therefore, the clinician should notify the laboratory of the possibility of listeriosis when sending placental or fetal cultures.

The greatest importance of listeriosis lies in its ready response to treatment with ampicillin. If diagnosed and treated early enough, fetal death can be prevented.[16] Even if it is not recognized until after the fetus has died, there exists the potential of treatment in a subsequent gestation.

Fetomaternal hemorrhage. The fact that fetal blood can gain access to the maternal circulation and thereby provoke a maternal immune response has been recognized for >40 years. Only relatively recently, however, has it been appreciated that such fetomaternal hemorrhage can be large enough to cause fetal exsanguination. Various types of trauma can be responsible, but in the majority of instances the pathophysiology is entirely unclear.

Laube and Schauberger[17] studied 29 women with unexplained fetal deaths by Kleihauer-Betke staining of peripheral blood and found four instances of massive fetomaternal hemorrhage, representing 150 to 240 ml of fetal blood (50% to 75% of total volume) in the maternal circulation.

Testing of maternal blood for fetal hemorrhage by either the Kleihauer-Betke technique or any of several other available methods should be done in all cases of

fetal death, particularly when no cause is apparent. Maternal blood must be drawn before induction of labor, amniocentesis, or other manipulation.

The significance of diagnosis of fetomaternal hemorrhage for a subsequent pregnancy is unknown, but it may have implications for immunoprophylaxis in cases of blood type incompatibility. At the very least it can provide an explanation of why the fetus died.

Lupus anticoagulant. Recently, it has become apparent that certain antiphospholipid antibodies are associated with a high frequency of fetal death and other forms of pregnancy loss. The most important of these antibodies is the so-called lupus anticoagulant, a particularly unfortunate term, since its association with lupus erythematosus is imperfect at best and its clinical effects are those of thrombosis rather than of anticoagulation. Closely related is the anticardiolipin antibody that seems to have similar effects.

The manner by which antiphospholipid antibodies affect pregnancy is unclear, but current thinking is that a vasculopathy involving the placenta and/or decidua is involved. In any case, the association with adverse pregnancy outcome is striking, particularly in view of the relatively short time it has been recognized. The most current review, on the basis of 15 retrospective reports published by 1985, documents 242 previous pregnancies in 65 women with lupus anticoagulant, of which 220 (91%) were lost as spontaneous abortion or fetal death.[18] In fact, only six cases have been reported in which a live birth occurred to a woman known to carry the lupus anticoagulant. The timing of fetal losses seems disproportionately high in the second and third trimester.

The screening test for lupus anticoagulant is the activated partial thromboplastin time. If this or other phospholipid-dependent tests show normal results, lupus anticoagulant can be excluded. If the activated partial thromboplastin time is positive (i.e., abnormally prolonged), it should be repeated after mixing with an equal volume of normal plasma to exclude a coagulation factor deficiency. With lupus anticoagulant, the addition of normal plasma will not correct the result to a near clotting time. Thus, if a patient has a prolonged activated partial thromboplastin time, which is unaffected by adding normal plasma, she probably has lupus anticoagulant. More specific tests have been described, but none has yet been used clinically.

The importance of identifying patients with lupus anticoagulant lies in the potential for pharmacologically ameliorating the otherwise abysmal pregnancy outcome. High-dosage glucocorticoid and low-dosage aspirin therapy has been described in relatively small series to promote live births (albeit these births usually are accompanied by preeclampsia, fetal growth retardation, and other complications) in the majority of treated cases.[19]

Another look at the second-assessment procedure for ovarian epithelial carcinoma

Donald G. Gallup, M.D., O. Eduardo Talledo, M.D., Michelle R. Dudzinski, M.D., and Keith W. Brown, D.O.

Augusta, Georgia, and Portsmouth, Virginia

Over a 10-year period, 65 of 196 patients (33%) with ovarian epithelial malignancy, previously treated with chemotherapy, had a second-look operation if the disease was clinically absent. All procedures were done by one of three gynecologic oncologists, and 48% of the patients had a positive second-look procedure. Of patients with original stage I, II disease, 25% had a positive second-look operation, contrasting with 61% of patients with stage III, IV. Significant perioperative morbidity occurred: one patient had intraoperative vascular collapse; 15% had prolonged ileus; 17% had small bowel resections at the time of the second-look operation or in the postoperative period. Of all patients with negative second-look operations, 24% have had recurrent disease from 5 to 23 months after the procedure. These recurrences were in the liver or distant sites in 63% of the patients. Second-look operations, if still indicated by negative noninvasive techniques, should be performed in tertiary care centers under study situations in a standard fashion. (AM J OBSTET GYNECOL 1987;157:590-6.)

Key words: Second-look, operation, ovarian cancer

The concept of second-look celiotomy for evaluation of presence or absence of disease was initially introduced by Wagensteen et al.[1] in patients who were previously treated for colon cancer. This procedure has become increasingly used during the past 2 decades in the "routine" management of patients with ovarian cancer.[2-10] The application of the term *second-look* procedures has been variable, but most current reports follow the criteria suggested by Ballon et al.[11]: (1) no clinical evidence of persistent carcinoma and (2) no radiographic evidence of persistent carcinoma. Second-look procedures, simply to assess disease status, are rarely advocated for patients with ovarian cancer who were previously treated by irradiation. Complications of the second-look procedure are numerous, with ileus and/or febrile morbidity listed as the most frequent.[2-7, 9, 10] Although laparoscopy, ultrasound, and computed tomography (CT) scanning may detect subclinical, persistent disease in some patients, these modalities are insufficient to assess disease status in most patients who have no clinical evidence of disease. This article reviews the experience at two medical centers in managing patients with epithelial ovarian carcinoma, who met the criteria as candidates for second-look laparotomy.

Material and methods

The clinical, tumor, and pathology records of all patients with a diagnosis of malignant ovarian tumors at the Medical College of Georgia, Augusta, Georgia, and the Naval Hospital, Portsmouth, Virginia, from January 1975 through December 1984 were reviewed. During the 10-year period, 236 patients were assessed with a diagnosis of ovarian cancer. Of these patients, 40 were initially excluded from the study group, since they had nonepithelial malignant tumors, such as gonadal stromal or germ cell tumors. All patients who underwent second-look procedures met the following criteria: (1) no clinical evidence of disease, (2) no prior radiation therapy, and (3) at least six courses of chemotherapy for known epithelial tumors. Reasons for not performing a second-look laparotomy or for including patients with another operation are noted in Table I. In general, progressive disease was considered a contraindication to second-look laparotomy. All patients who underwent a second-look operation were clinically free from disease on the basis of a thorough physical examination, liver function tests, and chest x-ray films. Most patients had an intravenous pyelogram and barium enema, and in the last 5 years of the study, patients also had pelvic and abdominal CT scans.

All second-look procedures were done under the supervision of one of three gynecologic oncologists (D. G. G., O. E. T., and M. R. D.). Celiotomy techniques

as described by others[2-10] were used for the second-look procedure. Following a generous midline incision, cell washings from the cul-de-sac, pericolic recesses, and diaphragms were done. Biopsies were done on these peritoneal surfaces and all adhesions. Any remaining greater omentum was removed. Any remaining infundibulopelvic ligaments were resected. Peritoneal surfaces adjacent to the infundibulopelvic and ipsilateral round ligament were also submitted for histologic evaluation. Samples of pelvic and/or para-aortic nodes were obtained in most patients. In the absence of gross tumor, between 15 and 40 tissue samples were submitted

for each patient. If patients had a gross tumor or frozen section evidence of tumor, the surgical procedure was usually terminated. Exceptions to this rule were in the rare patient in whom further debulking was deemed to be possibly beneficial. Specimens from all patients were presented to a gynecology, pathology, radiation oncology tumor conference, where review of histologic material was done and staging was assigned. If all specimens were negative for neoplasm, further chemotherapy was not given. One of the 34 patients with a negative second-look was treated with radioactive chromic phosphate. Patients with persistent disease were treated with a variety of second-line modalities.

Results

Of 196 patients with epithelial ovarian carcinomas, only 65 (33.2%) had a second-look laparotomy. Progressive disease during chemotherapy was the primary reason for not performing second-look procedures (Table I). Eight of the 196 patients (4.1%) refused a second-look and are alive, all more than 36 months, without evidence of recurrent disease. Five patients died of toxicity from chemotherapy and never had a second-look operation. Ten patients were operated on who had a known tumor, as further tumor reductive surgery was contemplated. Patients with early stage (I and II) tumors of low malignant potential were not included in the study group. However, nine patients

with stage III borderline tumors did have second-look procedures and were included.

The average age of the 65 study group patients was 46.9 years. White patients constituted 67.7% of the patients; black patients, 24.6%; and Malaysians, 7.7%. Patients with original stage I, II disease constituted 36.9% of the patients, as compared with 63.1% of patients with stage III, IV (Table II). Forty-eight percent of the patients had a positive second-look operation, and 10 of these 31 (32%) had only microscopic disease. One patient had a microscopic neoplasm noted in a paraaortic node only. Of patients with gross disease, 52% had widespread intra-abdominal metastases, 33% were thought to have disease confined to the pelvis, and three patients had palpable disease in the omentum or nodes. Of these latter 10 patients, disease could have been in other areas, since the procedure was usually terminated when a neoplasm was found. The chances of having a positive second-look operation was directly related to the original stage of the disease. Of patients with original stage I, II disease, 25% had a positive second-look, contrasting with 60.9% of patients with stage III, IV (Table II).

Other factors that might influence the possibility of having a positive second-look laparotomy were analyzed. Twenty-nine patients were aged ≤40 years, and 44.8% had a positive second-look operation, which contrasted with 19 of 36 patients (52.8%) over age 40 years who had a positive second-look laparotomy. Patients with grade 3 lesions constituted 61.3% of all patients with a positive second-look procedure. If a patient had a grade 3 carcinoma, she had a 63% chance of having a positive second-look procedure, compared with 20% for grade 1 (Table III). As expected, the vast majority of patients had a serous cystadenocarcinoma, and patients with serous tumors constituted 64.5% of all patients with a positive second-look procedure. If one had a serous tumor, chances of having a positive second-look operation were about 50%, which contrasted with 14% for mucinous tumors (Table IV). The amount of disease left behind at the original operation was clearly related to the positivity of the second-look operation. Eighty-seven percent of patients who had tumor nodules >2 cm left behind had a positive second-look procedure (Table V).

The majority of patients who had a negative second-look procedure were treated with a single alkylating agent, and most of these patients had early stage, early grade neoplasms (Table VI). The number of courses of treatment given did not influence the positivity or negativity of the procedure; 91% of the patients received from 8 to 12 courses of therapy. At the time of this analysis, all but six of 31 patients with a positive second-look procedure were dead from disease. Seventy-four percent were dead within 3 years of the original diagnosis. One patient died 42 months after the original diagnosis; one died 6 years afterward. Of the other six patients, one has been lost to follow-up and presumed dead. Two patients are without evidence of disease at 26 and 30 months after the institution of second-line chemotherapy. Both patients had grade 1 tumors with only microscopic disease found at the second-look laparotomy. Three patients have had positive third-look procedures and are alive but have disease, and all have tumors of low malignant potential, which were originally stage III.

All patients with a negative second-look laparotomy have had follow-up at least 30 months after the procedure. Eighty-two percent have had follow-up for more than 3 years. Of patients with negative second-look operations, 24% have had recurrent disease from 5 to 23 months after the procedure. These recurrences were in liver parenchyma or in distant sites in 63% of the patients (Table VII). All of these patients are dead from recurrent disease. Additionally, one patient with a negative second-look operation died of sepsis as a result of a chemotherapy-related myeloproliferative

Table VII. Characteristics of patients with recurrent cancer after negative second-look procedures

Patient	*Age*	*Original stage*	*Residual tumor after primary operation*	*Original grade*	*Histology of tumor*	*Interval to recurrence (mo)*	*Site of recurrence*
1	46	IV	≤2	3	Serous	7	Abdominal cavity
2	65	III	≤2	3	Adenocarcinoma, poorly differentiated	5	Lungs
3	56	III	≤2	3	Serous	14	Abdominal cavity, lesser sac
4	60	IIc	None	2	Serous	6	Abdominal cavity, liver parenchyma
5	49	III	≤2	2	Serous	8	Abdominal cavity

7	43	III	≤2	3	Serous	18	Lungs, liver, parenchyma
8	62	III	≤2	3	Serous	23	Cuff, liver, parenchyma

disorder. She had no clinical evidence of recurrent tumor.

Although no operative deaths were noted, significant perioperative morbidity occurred (Table VIII). Bowel resections after the second-look operation were required because of adhesions that caused small bowel obstruction. One patient had all but 48 inches (122 cm) of small bowel removed because of dense adhesions and tumor involvement. She had a normal preoperative computed tomography scan. The patient with vascular collapse had received only 400 mg/m^2 of Adriamycin. The average number of days spent in the hospital by patients undergoing second-look laparotomy was 8.3 with a range of 6 to 20.

Table VIII. Complications of second-look laparotomy

Complication	*No. of patients*	*Percent*
Ileus*	10	15.4
Small bowel resection required because of adhesions	9	13.8
Bowel resection required after second-look	2	3.1
EBL requiring transfusion†	10	15.4
Pulmonary (atelectasis)	2	3.1
Urinary tract infection	2	3.1
Wound infection	2	3.1
Intraoperative vascular collapse	1	1.6

EBL = Estimated blood loss.
*Ileus that requires nasogastric suction for >72 hours.
†Three of these patients lost >1000 ml of blood.

Comment

In this series, only those patients with second-look procedures for epithelial ovarian carcinoma were analyzed, and patients operated with a known tumor and the surgeon's intent of cytoreductive surgery were not included. Morbidity was significant, and a positive second-look procedure was noted in 48% of all patients. The great majority of patients with macroscopic disease at second-look procedures ultimately die from disease. "Routine" second-look procedures may not be indicated for all patients. There may be a select group of patients who are not candidates for second-look laparotomy. Is it possible to identify this group of patients?

Berek et al.[5] noted that patients aged <50 years tended to have negative second-look procedures. We found no such trend in this series of patients when those aged ≤40 years were compared with the older group. Positive second-assessment procedures were noted in 59% of patients adjuvantly treated with a combination of cyclophosphamide, Adriamycin, and cisplatin, as compared with 15% of patients treated with a single alkylating agent. The histologic type of tumor did not appear to affect the positivity of the second-look procedure, except for the small number of patients with mucinous tumors. Curry et al.[6] noted that patients with serous tumors had a 43% chance of having a positive second-look procedure, as did 54% of the patients reported by Roberts et al.[9] In the latter series, none of the seven patients with mucinous tumors had a positive second-look procedure.

Suboptimal resection of the tumor at the original operation was directly related to chances of having a positive second-look procedure, and this has been noted in almost every series of patients analyzed since 1980.[4, 5, 8-10, 12] Eighty-seven percent of the patients with residual tumors >2 cm reported here had a positive secondary surgical assessment. Several investigators have noted, as we did, that as the grade of the tumor increased, the chances of having a negative second-look procedure decreased.[4, 5, 8] In adding our patients to seven series of patients reported since 1980 with stage III, IV disease, the second-look procedure was positive in 70% of 371 patients (Table IX). The profile

Table IX. Outcome of second-look laparotomy in stage III, IV ovarian carcinoma

SLO = Second-look operation.

of a patient with a significant chance of having a positive second-look procedure includes anyone with a grade 3 lesion, with stage III neoplasm, and/or with suboptimal tumor resection at the original procedure. Every effort should be made to use noninvasive techniques to rule out persistent, recurrent disease in these high risk patients.

Debulking at the time of a second-look procedure in asymptomatic ovarian cancer patients with a known tumor is somewhat controversial. In a small number of patients, Vogl et al.[13] found that surgical resection of bulky ovarian cancer at second-effort surgery did not result in long-term survival of patients. Berek et al.[14] identified a group of patients who would not benefit from secondary cytoreductive surgery: those with >1.5 cm of tumor left behind after the original procedure; those with >1000 ml of ascites or those with tumor size noted at the second-effort procedure to be >5 cm; and those with clinical evidence of recurrence. Copeland et al.[15] noted prolonged progression-free intervals and a 5-year survival of 85% in patients with only microscopic disease found at second-look laparotomy. No comment can be made regarding the efficacy of tumor reductive surgery at second-effort procedures in the patients reported in this article.

CT scan, along with fine-needle aspiration, was helpful in identifying a tumor, precluding a second-look operation in only five of our patients (Table I). In the absence of specific symptoms, a barium enema or an intravenous pyelogram was not helpful in identifying nonpalpable tumors. A CT scan with contrast should provide as much information as isolated contrast studies. CT may be helpful in identifying parenchymal liver lesions, omental involvement, or ascites that is not clinically evident.[16] CT is incapable of accurately detecting tumor nodules <1 cm, and the false-negative rate is extremely high. Anatomic distortion from prior surgery may yield false positive results; positive CT findings should be confirmed by fine-needle aspiration. A normal CT cannot replace a second-look procedure for accurate assessment of the status of the disease. After administering anesthetic to the patient, careful pelvic examination with transvaginal fine-needle aspiration before laparotomy may be of help. Cul-de-sac aspiration cytology has been shown to have as high as a 92% correlation when compared with second-look laparotomy.[17] This technique is well-tolerated by patients and is certainly of value if aspiration cytology is positive. A sensitive serologic tumor marker for evaluation of disease status and determination of the presence of persistent carcinoma would be an ideal monitoring tool. Niloff et al.[18] noted that a calcium 125 level >35 U/ml was a strong predictor of the presence of disease. Patients with high levels of calcium 125 could be spared a second-look operation. A positive laparoscopy can avoid more extensive operations in about one third of patients with ovarian cancer.[19] However, a negative or inadequate procedure is not sufficient to rule out persistent disease, as there are obviously limitations of observations of the anterior abdominal wall and retroperitoneal lymph nodes.

No one in this series had a second assessment procedure after irradiation, but major complications were noted in a significant number of patients. Febrile morbidity, wound infections, and ileus are the complications most frequently noted, but the details of complications are not given in some reports. One report from England noted that 70% of 50 patients had ileus, 54% required transfusions, and one had a bowel resection.[7] A report from Schwartz and Smith[3] indicated 9% had wound infections, 5% had bowel injuries or obstruction, and 8% had significant hemorrhage. Roberts et al.[9] noted a 4% incidence of ileus, a 7% incidence of wound infections, and 4% who required transfusion. One patient had a bowel obstruction. These complications reported here and by others underscore the need for further development of noninvasive methods to detect subclinical recurrences.

Of the 34 patients with a negative second-look laparotomy, 24% have had a recurrence. This figure is not much different from other reports, ranging from a low recurrence rate reported by Webb et al.[4] and Barnhill et al.[8] of 12.5% to a high of 22.2% reported by Berek et al.[5] All of our patients had recurrences within 23 months of the second-assessment operation. Most patients with a recurrence will manifest disease within 2 years of the second-look operation,[5,6] although Barnhill et al.[8] reported recurrences in two of six patients after a period of 3 years. Two of their six patients with recurrence had endometrioid tumors, whereas all but one of our patients with recurrence had serous tumors. Roberts et al.[9] noted that residual disease after original tumor-reductive surgery was a very important factor

in patients who developed a recurrence after a negative second-look procedure. If residual disease was present, 60% recurred, as opposed to 7% who had no residual disease. Only one of our eight patients with recurrence had no gross residual disease after the original procedure. The second-look laparotomy should be thorough and should include pelvic and para-aortic lymph node sampling. Berek et al.[5] have reported patients with isolated microscopic disease in retroperitoneal nodes without evidence of intraperitoneal disease at the time of second-look laparotomy. All of the patients with negative second-look operations reported here, who later had recurrences, had at least pelvic node sampling. Certain factors are associated with an increased risk of recurrence: (1) stage III disease or more, (2) any residual disease after the original tumor-reductive surgery, (3) advanced grade of tumor, and (4) serous tumors.

Sixty-three percent of our patients with a negative second-look procedure had a later recurrence in the liver or distant sites. Others[5, 8] have also reported recurrences in the liver and inguinal nodes. Regular follow-up at close intervals is indicated in patients with negative second-look procedures and should include chest x-ray films, serum tumor markers when available, liver function studies, and CT scans, in addition to careful pelvic examination.

In summary, patients with early stage, low grade lesions are at low risk for having a positive second-look procedure, as are patients with early stage mucinous cystadenocarcinoma. Patients with grade 3 lesions, stage III lesions, and/or suboptimal resection of the original tumor should undergo every available screening test before submitting themselves to a second-look procedure, since more than two-thirds will have a positive second-look result. Survival of patients with a gross tumor at a second-look operation appears to be dismal, no matter what second-line treatment is given. Second-look celiotomy is not a procedure without major complications and should be performed in tertiary care centers. A group of patients can be identified who are at greatest risk to have a recurrence after a negative second-look procedure and includes those with advanced stage, high grade serous tumors who have any residual tumor left behind at the original procedure.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

DR. KENNETH MUHLENDORF, Norfolk, Virginia (Official Guest). Dr. Gallop and his colleagues have shared with us a multi-center retrospective review of a large number of patients undergoing second-look procedures for ovarian epithelial cancer over a 10-year period. In addition to the usual reporting of patient outcome, Dr. Gallop also considers the significant morbidity of these operations and the unfortunate 24% of patients who have a relapse within 2 years after a negative second-look procedure.

There are several lessons to be learned from this study that apply directly to gynecologists who provide primary care. This article stresses the necessity for a

meticulous investigation before a second-look operation is done. It is indeed frustrating that so many patients who undergo these operations have lethal amounts of disease remaining for which so little can be done. I was fascinated by the suggestion of using cul-de-sac aspiration cytology to help detect microscopic disease before surgery. Do you think the day will come when cul-de-sac aspirated cells can be grown in tissue culture, much as amniotic fluid cells are grown, and then used to determine the best treatment regimen, much as we do with urine culture and sensitivities?

As others have shown, the response to initial chemotherapy and the probability of a negative second-look operation increased significantly if the first surgery removed all of the disease. In this study, where there was no residual disease, 71% of the patients had a negative second-look procedure. Unfortunately, ovarian epithelial malignancy cannot be diagnosed accurately with preoperative studies. Often enough, a surgeon finds himself confronted with complex intra-abdominal disease that requires skill outside of the experience of many pelvic surgeons in practice. To obtain the results presented in this article, a high index of suspicion and appropriate referral to tertiary care physicians are essential.

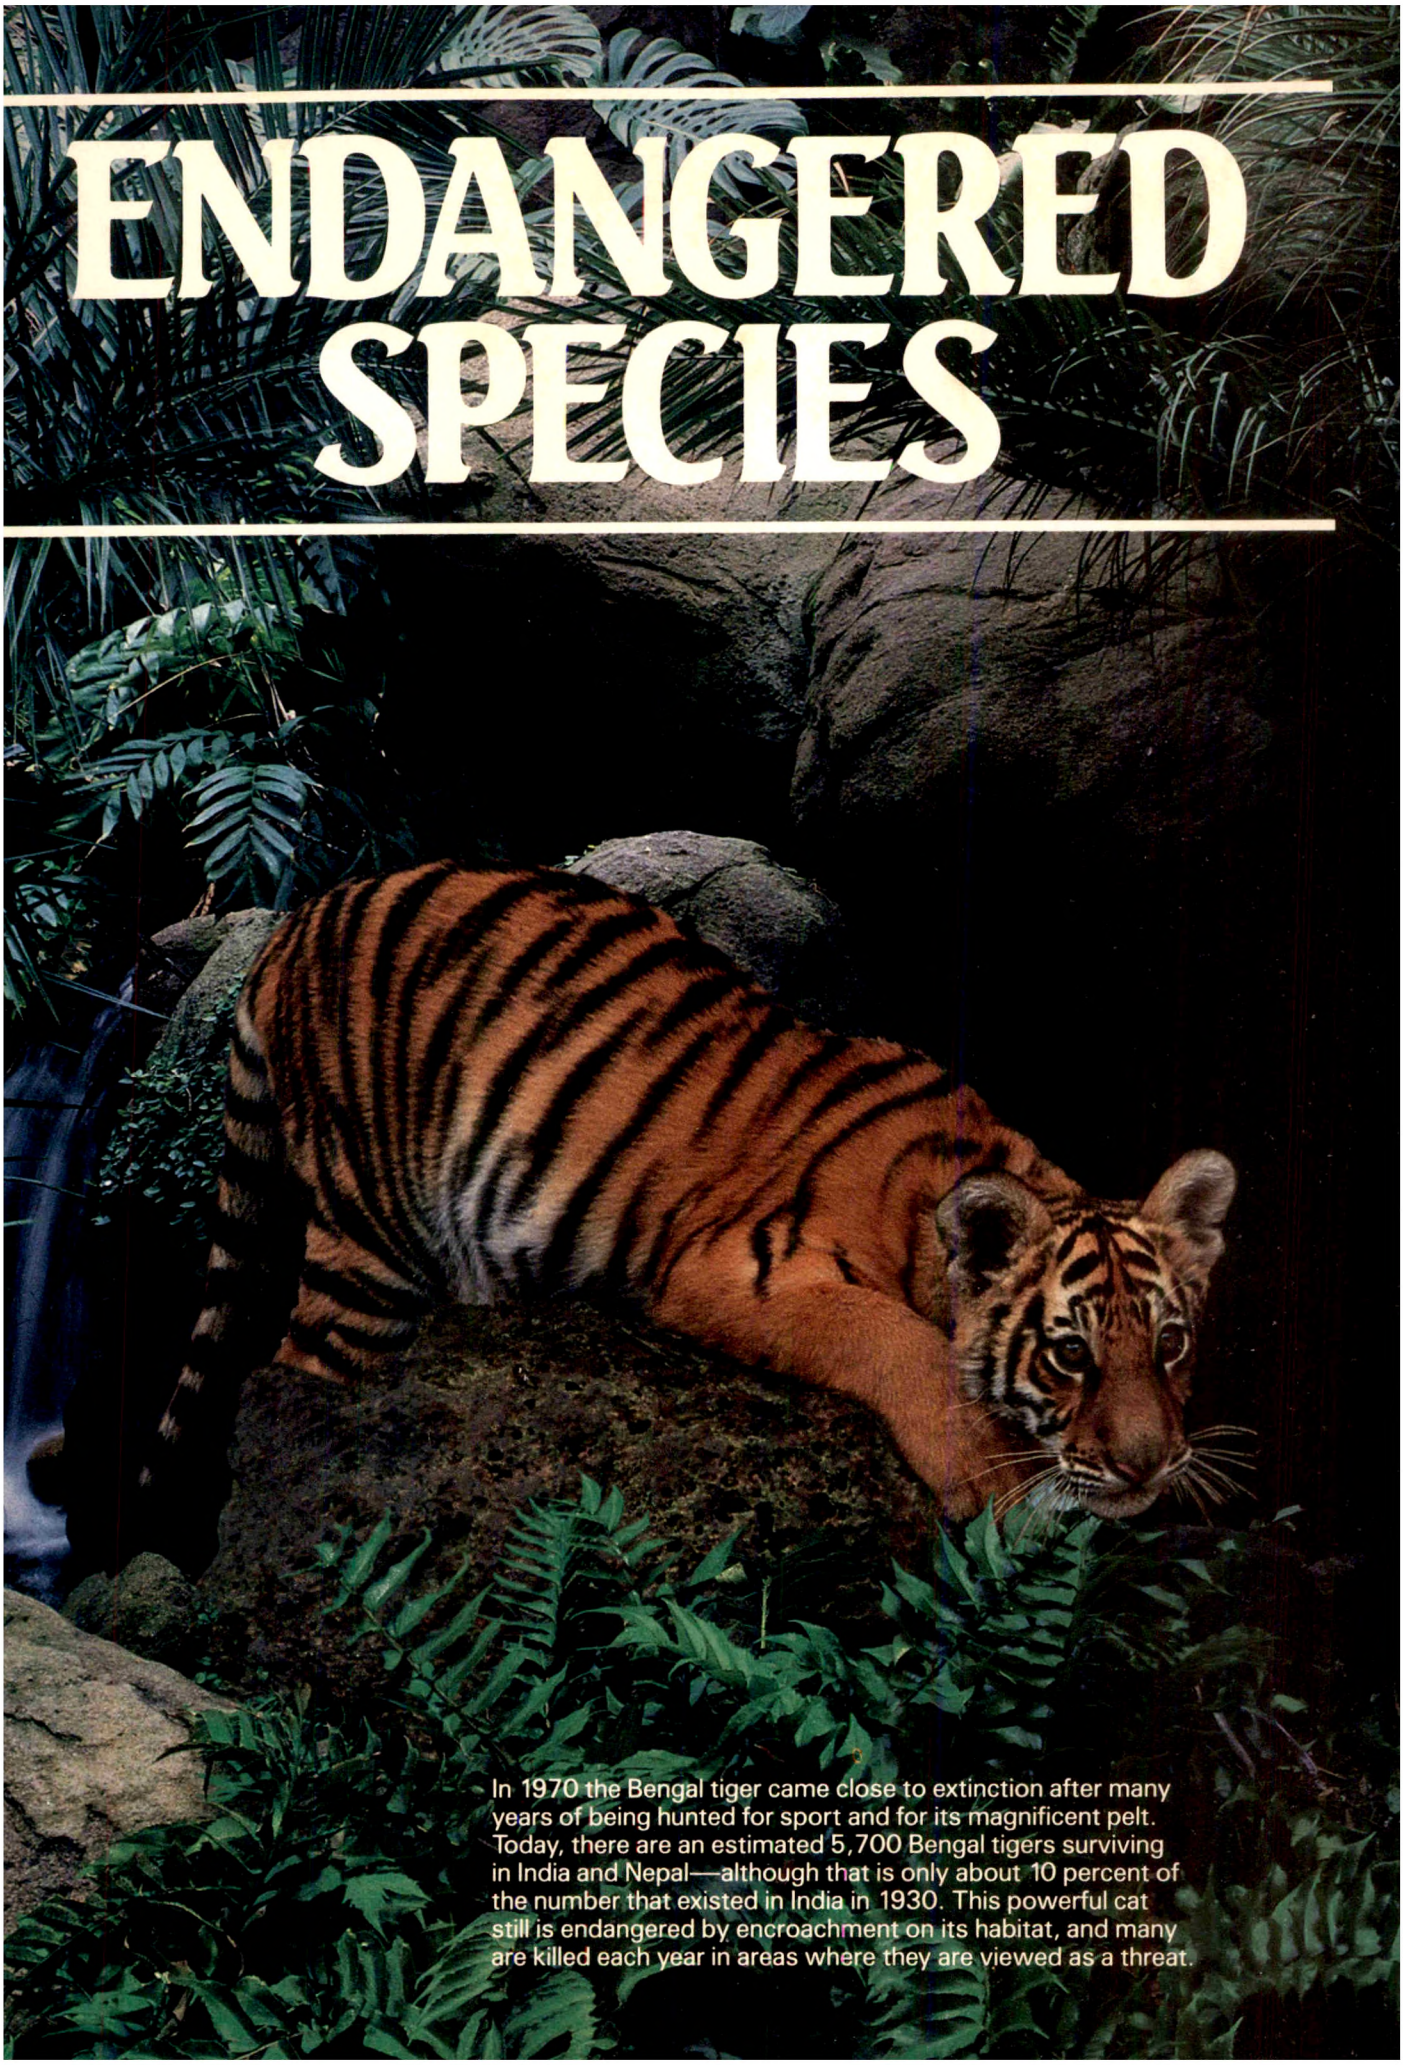
Patients in this study who are treated with a single alkylating agent were more likely to have a negative second-look procedure than those treated with combination chemotherapy. Do you find that the overall long-term survival remains better with single agent therapy?

The great weakness of the second-look procedure is the relatively few patients who actually benefit. Because the intended goal is to find the patient for whom all treatment may stop, the high morbidity, not to mention the cost of this surgery, pleads for some magic bullet. Calcium 125 is not sensitive or specific enough. Modern CT scans provide resolution to 1 cm but cannot differentiate the enlarged lymph node from one that contains a tumor. It appears that magnetic resonance imaging cannot provide a signal intensity sufficient to detect subclinical ovarian cancer. Just as the CT scan is proving in many cases to have more value than the intravenous pyelogram, perhaps soon the use of antibodies with ovarian tumor antigens can replace the second-look procedure.

Until the perfect tumor marker is discovered or created in the laboratory, the gold standard for determining the cure of ovarian cancer remains the meticulously performed second-look operation done by a skilled surgeon with a skilled pathologist. With this must be added the inevitable variable of time, for it is the longevity of the disease-free interval that ultimately allows one to declare a patient cured.

I congratulate Dr. Gallop for a thorough review of an accepted technique with attention to its limitations and its complications.

Dr. Paul B. Underwood, Charlottesville, Virginia. I would like to ask you two questions. (1) Was there a difference in the recurrence rate in the patients treated with single agent Alkeran as compared with your count? (2) On the negative second-look operations, do you treat those patients with any further methods?



Dr. Matthew Burrell, Atlanta, Georgia. Did you find any higher risk for the clear cell adenocarcinoma? Our group has found that clear cells are a very high risk predictor of residual findings on second-look procedures.

Dr. William T. Mixson, Coral Gables, Florida. Questions are being asked by the oncologist. As a generalist I am sitting here thinking that this is almost an article that says that a second-look operation may not be very good. How many of these people are helped? How many benefit from the use of the second-look operation?

Dr. Gallup (Closing). The value of cul-de-sac aspiration cytology was recognized by Dr. Keetle many years ago. In fact, drug sensitivity is in its infancy. It may help us in the future. Other reports, besides ours, indicate significant long-term survival in patients treated with single alkylating agents. In general, these patients all have early grade, early stage lesions. Recent work in this country leans toward recommendations for multi-agent drug therapy for the majority of patients with advanced epithelial ovarian tumors. We may not be really improving the walking, talking 5-year survival, but we are improving the progression-free interval. Ten years ago, a patient may have died within 2 years of diagnosis. Now, a patient with a similar lesion may live a few years longer with fairly good quality of life. Dr. Burrell, we had no patients with clear cell tumors, so I cannot comment.

Dr. Underwood asked about treatment options for the patients with a negative second-look operation. Dr. Dudzinski, who relieved me at Portsmouth Naval Hospital, did treat one patient in this series with radioactive intraperitoneal chromic phosphate. At the Medical College of Georgia, we are selecting a group of high risk patients who probably should be treated. Maybe we should give them "three for the road," as we have done with gestational trophoblastic disease. Other options include intraperitoneal immunotherapy or chemotherapy. Remember, about one quarter of patients with appropriate negative second-look operations will have a recurrence. Whichever methods are chosen, patients should be carefully randomized. Dr. Mixson, I believe we must be very careful in selecting patients on whom we operate. If you believe it is a bulk tumor, why operate? On the other hand, patients with intestinal obstruction may benefit in select situations. Another procedure to relieve symptoms may be helpful in a few patients.

ENDANGERED SPECIES

In 1970 the Bengal tiger came close to extinction after many years of being hunted for sport and for its magnificent pelt. Today, there are an estimated 5,700 Bengal tigers surviving in India and Nepal—although that is only about 10 percent of the number that existed in India in 1930. This powerful cat still is endangered by encroachment on its habitat, and many are killed each year in areas where they are viewed as a threat.

ENDANGERED SPECIES?

Is the practice of obstetrics endangered? Its survival is threatened by factors that are likely to diminish significantly the number of practicing obstetricians. The continuing increase in the number of malpractice lawsuits against physicians and the corresponding inflation of liability insurance premiums have plunged the obstetrics specialty into a crisis.

Patient-initiated litigation is now so common that 1 in 6 obstetrician/gynecologists is sued each year, compared with 1 in 20 only ten years ago. As a result, obstetricians pay three to four times more for malpractice insurance than do physicians in most other specialties.

Survival of the practice of obstetrics is further jeopardized because fewer students are entering the specialty and the number of experienced physicians leaving obstetrics or retiring early is on the rise. For many physicians, this crisis has taken the joy out of practicing medicine.

Immediate action is essential in order to preserve the practice of obstetrics. In response to this need, G.D. Searle & Co. has organized the Searle Alliance for Health Care. This initiative is helping to lead a national effort to resolve the medical professional liability crisis.

PROFESSIONAL EXCHANGE: PRESERVATION THROUGH EDUCATION

One exciting component of the Searle Alliance for Health Care is Professional Exchange, a series of monthly telephone conferences. Acting as a national network, the interactive conferences facilitate discussion about professional liability among physicians and experts. Professional Exchange is designed to provide obstetrician/gynecologists with current and useful information as it relates to running a practice.

Host of this pioneer program will be Daniel K. Roberts, M.D., Ph.D., Professor and Chairman of the Department of Obstetrics and Gynecology at Wesley Medical Center, University of Kansas School of Medicine, in Wichita, Kansas. Both of Dr. Roberts' guests for September are from the American College of Obstetricians and Gynecologists. They are Kenneth V. Heland, J.D., Associate Director, Department of Professional Liability, and Jimmie A. Gleason, M.D., Chairman, Professional Liability Board. Together they will discuss ACOG's legislative activities and professional liability resource services. Join them in this interactive telephone conference on **September 22, 1987,** by dialing the numbers given below.

On **October 20,** Curtis L. Cetrulo, M.D., Professor of Obstetrics and Gynecology, Tufts University School of Medicine, Boston, will explore the topic of obstetric risk management.

At 7 p.m. EDT, call 1-900-200-9600 (toll free)* to listen, or dial 1-800-248-3233 to participate. For more information about Professional Exchange or the Searle Alliance for Health Care, contact your Searle representative.

Seeking resolution of the professional liability crisis

Demulen 1/35™
(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

*Until 6 p.m. Eastern time of the day following each telephone conference, you can call, on the hour, 1-900-200-9600 to hear an unedited version of the previous evening's program.

Please see the last page of this advertisement for a brief summary of the complete prescribing information.

© 1987, Searle & Co.

7AO58T

Demulen 1/35™

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers	10.2	2.6		62.0	15.9
≥15 cigarettes daily	13.0	5.1		78.7	31.3
<15 cigarettes daily	4.7	0.9		28.6	5.7
Nonsmokers	1.8	1.2		10.7	7.4
Smokers and nonsmokers	5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low. Age:	<30	30-39	≥40
Heavy smokers (≥15/day)	C	B	A
Light smokers (<15/day)	D	C	B
Nonsmokers, no predispositions	D	C,D	C
Nonsmokers, with predispositions	C	C,B	B,A

Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycystic ovaries) occurr nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer w combination or progestogen-only OCs, though individual cases were reported. Studies show no increased breast cancer with OCs or estroge However, greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk of bre cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens rose and further increas with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other risk factors. Decrease in benign bre tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term use Cervical microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increased canc risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consic nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of breast canc or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** *Hepatic adenomas, e* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk, as was age ov 30. Though benign, these lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk duration of use, being much greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,00 Consider such lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to half wi acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT m be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. OCs are contraindicated in case of past present, benign or malignant liver tumors developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy, bir defects, malignancy in offspring:* Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in ute to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, monit such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. DE exposed daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Other estroger may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL for vertebral, anal, cardia tracheoesophageal, renal, and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of limi reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threatene abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, includin OCs, during early pregnancy occurred in 19.2/1,000 births, compared to 7.8 for those unexposed ($P<.05$). More twinning was reported conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but there is considerabl evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion increased soon after stopping OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not bee demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods ar missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy shoul use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not us progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 years use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydrate and lipid metabolism:* Decreasec glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides and tota phospholipids may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few months, and degree may relate to progestoger dose. Hypertension prevalence in users is not higher in the first year, but increases with longer exposure; in the 5th year it is 2½—3 time the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), preexisting rena disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weigh gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Eve though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors fo cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of migraine o development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating cause. **10.** *Bleedin irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregula bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology i excluded, time or change to another product may suffice. Change to a higher-estrogen OC only when necessary as this may increase thromboembolic risk. Those with history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatory or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has been associated with postpill amenorrhea. One study reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients with postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of ectopic to intrauterine pregnancies is no higher than in nonusers. There may be increased risk of ectopics after discontinuing. **12.** *Breast feeding:* OCs may decrease quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs until after weaning. **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable difference in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 months and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete history and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uterine leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Fluid retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic, or renal dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestatic jaundice occurred after OC and troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized in liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblastic anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use when submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have been observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, IX, X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroid hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4, decreased pregnanediol excretion; reduced metyrapone response; increased blood transcortin, corticosteroid, triglyceride, phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influence of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask onset of climacteric. Cervical chlamydial prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients.* See patient labeling. *Drug interactions:* OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycin, penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidone, phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizers, tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophen. **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis and thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The following are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhea during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargement, secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice, migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change in corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for: premenstrual-like syndrome, cataracts, libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis, fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic uremia, malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVCs, abnormal EKG, pulmonary hypertension. TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumatoid arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, and breast carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea and withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use and is available on request.**

27th ANNUAL REVIEW COURSE IN OBSTETRICS AND GYNECOLOGY

October 26 through 30, 1987

(Monday-Friday)

at the St. Regis-Sheraton Hotel, New York, New York

36 Credit Hours, Category 1, A.M.A.'s Physician's Recognition Award; 36 Cognates by American College of Obstetricians & Gynecologists; and 36 Elective Credits from the American Academy of Family Physicians.

FEE $775 (residents $470); includes syllabus, luncheons, and refreshments

Conference Director: **EDWARD T. BOWE, M.D.**

MORTIMER G. ROSEN, M.D., associates, and the following guest lecturers:

HUGH R.K. BARBER, M.D. **MILTON H. GOLDRATH, M.D.** **WALTER E. JONES, M.D.**
ROBERT C. CEFALO, M.D. **ROBERT B. JAFFE, M.D.** **BYRON J. MASTERSON, M.D.**

Survey of the major clinical and pathological problems pertaining to the female reproductive system. The new format is designed for practicing clinicians and for candidates for the Board Examinations. Emphasis is placed on the diagnosis and management of obstetrical and gynecological disorders, including infertility, endocrine problems, malignant diseases, and updates of the common everyday problems of clinical management. The course is divided as follows: maternal-fetal medicine, gynecology and gynecological surgery, gynecological oncology, reproductive endocrinology including infertility, diagnostic techniques such as advanced pelvic and vaginal ultrasound, laparoscopic and hysteroscopic techniques, and laser therapy. **The Third Annual Raymond L. Vande Wiele Memorial Lecture** will be presented by Robert B. Jaffe, M.D., on Thursday, October 29, at 1:15 p.m.

Contact: Center for Continuing Education, 630 West 168th Street, N.Y., N.Y. 10032; telephone (212) 305-3682.

Journal of Developmental Physiology

Editor: Colin T. Jones, Nuffield Institute for Medical Research, University of Oxford

The *Journal of Developmental Physiology* presents the results of original research on the anatomical, biochemical, endocrine, pharmacological, and physiological aspects of the scientific study of pregnancy, the fetus, or the neonate of man or experimental animals. It covers the period from the embryo to the infant and the associated changes in the maternal organism during that time. A primary aim of the journal is to promote the communication of scientific information between individuals studying various aspects of development.

Volume 10, 1988 (6 issues) ISSN 0141-9846

Cefizox®

brand of

sterile ceftizoxime sodium and ceftizoxime sodium injection

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

'Cefizox' is indicated in the treatment of infections due to susceptible strains of the microorganisms listed below:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Klebsiella* sp.; *Proteus mirabilis; Escherichia coli; Haemophilus influenzae* including ampicillin-resistant strains; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Serratia* sp.; *Enterobacter* sp.; and *Bacteroides* sp.

URINARY TRACT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Pseudomonas* sp. including *Ps. aeruginosa; Proteus mirabilis; P. vulgaris; Providencia rettgeri* (formerly *Proteus rettgeri*) and *Morganella morganii* (formerly *Proteus morganii*); *Klebsiella* sp.; *Serratia* sp. including *S. marcescens; Enterobacter* sp.

GONORRHEA. Uncomplicated cervical and urethral gonorrhea caused by *Neisseria gonorrhoeae.*

INTRA-ABDOMINAL INFECTIONS caused by *Escherichia coli; Staphylococcus epidermidis; Streptococcus* sp. (excluding enterococci); *Enterobacter* sp.; *Klebsiella* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

SEPTICEMIA caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Bacteroides* sp. including *B. fragilis; Klebsiella* sp.; and *Serratia* sp.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Staphylococcus epidermidis; Escherichia coli; Klebsiella* sp.; *Streptococcus* sp. including *Streptococcus pyogenes* (group A beta-hemolytic), but excluding enterococci; *Proteus mirabilis; Serratia* sp.; *Enterobacter* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

BONE AND JOINT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Streptococcus* sp. (excluding enterococci); *Proteus mirabilis; Bacteroides* sp.; and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

MENINGITIS caused by *Haemophilus influenzae.* 'Cefizox' has also been used successfully in the treatment of a limited number of pediatric and adult cases of meningitis caused by *Streptococcus pneumoniae.*

'Cefizox' has been effective in the treatment of seriously ill, compromised patients, including those who were debilitated, immunosuppressed or neutropenic.

Many infections caused by aerobic gram-negative organisms and by mixtures of organisms resistant to other cephalosporins, aminoglycosides, or penicillins respond to treatment with 'Cefizox'.

Because of the serious nature of some urinary tract infections due to *Ps. aeruginosa* and because many strains of *Pseudomonas* species are only moderately susceptible to 'Cefizox', higher dosage is recommended. Other therapy should be instituted if the response is not prompt.

Susceptibility studies on specimens obtained prior to therapy should be used to determine the response of causative organisms to 'Cefizox'. Therapy with 'Cefizox' may be initiated pending results of the studies; however, treatment should be adjusted according to study findings. In serious infections 'Cefizox' has been used concomitantly with aminoglycosides (see Precautions). Before using 'Cefizox' concomitantly with other antibiotics, the prescribing information for those agents should be reviewed for contraindications, warnings, precautions and adverse reactions. Renal function should be carefully monitored.

CONTRAINDICATIONS

'Cefizox' is contraindicated in persons who have shown hypersensitivity to cephalosporin antibiotics.

WARNINGS

BEFORE THERAPY WITH 'CEFIZOX' IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who developed diarrhea in association with antibiotic use. Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of *Clostridia.* Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro.* Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile.* Other causes of colitis should also be considered.

PRECAUTIONS

General: As with all broad-spectrum antibiotics, 'Cefizox' should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Although 'Cefizox' has not been shown to produce an alteration in renal function, renal status should be evaluated, especially in seriously ill patients receiving maximum dose therapy. As with any antibiotic, prolonged use may result in overgrowth of nonsusceptible organisms. Careful observation is essential; appropriate measures should be taken if superinfection occurs.

Drug Interactions: Although the occurrence has not been reported with 'Cefizox,' nephrotoxicity has been reported following concomitant administration of other cephalosporins and aminoglycosides.

Pregnancy: (Category B.) Reproduction studies have been performed in rats and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to 'Cefizox'. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery: Safety of 'Cefizox' use during labor and delivery has not been established.

Nursing Mothers: 'Cefizox' is excreted in human milk in low concentrations. Caution should be exercised when 'Cefizox' is administered to a nursing woman.

Infants and Children: Safety and efficacy in infants from birth to six months of age have not been established. In children six months of age and older, treatment with 'Cefizox' has been associated with transient elevated levels of eosinophils, SGOT, SGPT and CPK (creatine phosphokinase). The CPK elevation may be related to I.M. administration.

ADVERSE REACTIONS

Ceftizoxime is generally well tolerated; the *most* frequent adverse reactions (*greater than* 1%, but less than 5%) are: *Hypersensitivity*—Rash, pruritus, fever. *Hepatic*—Transient elevation in SGOT, SGPT and alkaline phosphatase. *Hematologic*—Transient eosinophilia, thrombocytosis. Some individuals have developed a positive Coombs test. *Local*—Injection site—Burning, cellulitis, phlebitis with I.V. administration, pain, induration, tenderness, paresthesia.

Less frequent adverse reactions (*less than* 1%) are: *Hypersensitivity*—Numbness has been reported rarely. *Hepatic*—Elevation of bilirubin has been reported rarely. *Renal*—Transient elevations of BUN and creatinine have been occasionally observed with ceftizoxime. *Hematologic*—Anemia, leukopenia, neutropenia and thrombocytopenia have been reported rarely. *Genitourinary*—Vaginitis has rarely occurred. *Gastrointestinal*—Diarrhea; nausea and vomiting have been reported occasionally. Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment. (See Warnings.)

HOW SUPPLIED

Cefizox (sterile ceftizoxime sodium, FSK) is supplied in vials equivalent to 1 gram or 2 grams of ceftizoxime; in "Piggyback" Vials for I.V. admixture equivalent to 1 gram or 2 grams of ceftizoxime.

Cefizox (ceftizoxime sodium injection, FSK) as a frozen, sterile, nonpyrogenic solution in plastic containers—supplied in 50 ml. single-dose containers equivalent to 1 gram or 2 grams of ceftizoxime, in 5% Dextrose (D5W). Do not store above -20°C.

'Cefizox' supplied as a frozen, sterile, nonpyrogenic solution in plastic containers is manufactured for Fujisawa SmithKline Corporation by Travenol Laboratories, Inc., Deerfield, IL 60015.

Endometrial metaplasia associated with endometrial adenocarcinoma

Willie A. Andersen, M.D., Peyton T. Taylor, Jr., M.D., Robert E. Fechner, M.D., and Jo Ann V. Pinkerton, M.D.
Charlottesville, Virginia

Endometrial metaplasia is a complex group of epithelial proliferations. The relationship of metaplasia, other than squamous metaplasia, to endometrial adenocarcinoma has not been clearly established. Between 1969 and 1979, 183 patients diagnosed as having Stage I endometrial adenocarcinoma (according to International Federation of Gynecology and Obstetrics) were treated at the University of Virginia Medical Center. Sixty of the patients were treated with hysterectomy without preoperative irradiation. A histopathologic review was performed without knowledge of the clinical outcome and subsequent clinopathologic correlations were analyzed. On review, 32/60 had carcinoma without metaplasia and 15/60 had both carcinoma and metaplasia. Thirteen of the 60 patients were judged not to have cancer: 12 had both hyperplasia and metaplasia and one had hyperplasia without metaplasia. None of the 12 patients reclassified as having metaplasia had a recurrence or died of endometrial carcinoma. Patients with both metaplasia and carcinoma were significantly younger than patients with only carcinoma and the associated carcinomas were more frequently well differentiated. (AM J OBSTET GYNECOL 1987;157: 597-604.)

Key words: Endometrial carcinoma, endometrial metaplasia

The human endometrium has a very wide range of histologic expressions in normal, hyperplastic, and neoplastic conditions. In spite of extensive studies spanning several decades, there is still controversy over the histologic criteria of endometrial adenocarcinoma.[1-3] In 1980 an additional complication was added by Hendrickson and Kempson[4] when they described the range of benign proliferative changes of the endometrium which they collectively called "nonneoplastic endometrial metaplasias." Although the familiar "squamous" metaplasia was included in their work, the focus was on "new" metaplastic processes, which included eosinophilic, mucinous, papillary, tubal, and clear cell types. Does the identification or segregation of these metaplastic changes have any importance or does it only add further confusion? This report reviews cases in which the diagnosis was Stage I adenocarcinoma of the endometrium with treatment by hysterectomy and discusses the relationship of metaplasia to carcinoma in these patients.

Material and methods

Between 1969 and 1979, 183 patients with Stage I adenocarcinoma of the endometrium (International Federation of Gynecology and Obstetrics, FIGO) were identified through the tumor registry of the University of Virginia Medical Center. During this time period, 123 patients with adenocarcinoma clinically confined to the uterus were treated with preoperative radiation followed by exploration and hysterectomy. For this reason, there were only 60 cases where there was a hysterectomy specimen without the confounding changes of irradiation. All available histologic material from the endometrial biopsy or curettage and the hysterectomy specimen was reviewed without knowledge of the previous diagnosis, treatment, or clinical course of the patient. The clinical records were abstracted, coded, and analyzed by use of the Statistical Package of the Social Sciences system of the Vogelbach Computing Center of Northwestern University, Version 9.0, 1984. Statistical significance was determined by χ^2 analysis of contingency tables. Statistical significance was set at the 5% probability level.

All cases were staged as FIGO Stage I. After hysterectomy, 17 patients received postoperative radiation therapy after surgical-pathologic correlation. No patients were lost to follow-up.

The criteria for diagnosis of the various forms of metaplasia were those of Hendrickson and Kempson.[4] Representative photomicrographs of metaplasia are illustrated in Figs. 1 to 4.

The designation of hyperplastic endometrium required abnormal amounts of proliferative endometrial tissue, architectural complexity, or cytologic atypia. The

classical adjectives of "cystic glandular," "adenomatous," and "atypical" were used.

The designation of adenocarcinoma required architectural and cytologic abnormalities as defined by Hendrickson and Kempson.[5]

Results

The diagnosis and interrelationship of metaplasia and cancer are given for both the biopsy/curettage specimen (Table I) and the hysterectomy specimen (Table II).

After the above criteria were applied, the diagnosis on the curretings from 13 patients (21%) was changed from carcinoma to hyperplasia without carcinoma. Eight had hyperplasia with atypia, four had adenomatous hyperplasia without atypia, and one had cystic hyperplasia without atypia. Eleven of these patients also had metaplasia. Six of the eight with hyperplasia and atypia had metaplasia as did all four of those with adenomatous hyperplasia and the one patient with cystic hyperplasia. None of these patients had carcinoma in the hysterectomy specimen and none had recurrence

Fig. 3. Eosinophilic metaplasia, which includes a cuboidal cell with eosinophilic cytoplasm and a centrally located, normal nucleus. The cells are all the same size and surrounded by endometrial stroma. (Hematoxylin and eosin. Original magnification ×125.)

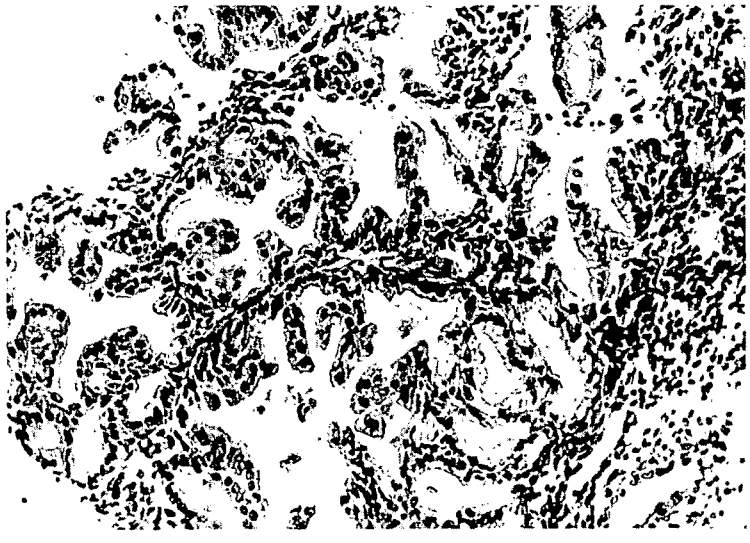

Fig. 4. Mucinous metaplasia that has small cells with basal nuclei and mucus-filled cytoplasm on the luminal side of the cell. Variable amounts of endometrial stroma are adjacent to the stroma. (Hematoxylin and eosin. Original magnification ×125.)

or died of endometrial carcinoma. The median follow-up for this group is 80 months with a range of 25 to 139 months.

Forty-seven patients had endometrial carcinoma on curettage (Table I). Thirty-two had carcinoma without metaplasia and 15 had both carcinoma and metaplasia. The most common pattern of carcinoma was endometrioid (28 patients). This was followed by "mixed" carcinomas (10 patients), serous papillary carcinoma (four patients), adenosquamous carcinoma (two patients), clear cell carcinoma (two patients), and poorly differentiated small cell malignancy (one patient). All 10 cases of "mixed" carcinoma had an endometrioid component; eight cases had a serous papillary component and two cases had a mucinous component.

The types of endometrial carcinoma associated with the presence or absence of metaplasia are shown in Table III. Although no statistically meaningful correlation could be drawn, there was always some component of "endometrioid" carcinoma associated with metaplasia.

The different patterns of metaplasia varied between

Table I. Review diagnoses of endometrial biopsy/curettage specimens (N = 60)

Carcinoma on curettings	*Metaplasia on curettings*		
	Yes	*No*	*Total*
Yes	15	32	47
No	11	2	13
Total	26	34	60

Table II. Review diagnoses of hysterectomy specimens (N = 60)

Carcinoma in uterus	*Metaplasia in uterus*		
	Yes	*No*	*Total*
Yes	15	25	40
No	12	8	20
Total	27	33	60

the curettage and the hysterectomy specimen (Tables IV and V), probably reflecting a greater amount of histologic material for study in the latter. Although metaplasia was commonly seen as a single type, multiple types were seen in 52% of the curettage samples and 42% of the hysterectomy samples. There was no single type or combination of types of metaplasia more likely to be associated with malignancy. Both eosinophilic and ciliated metaplasia were found more frequently than squamous metaplasia.

When metaplasia and malignancy coexisted in a curettage specimen, the malignancy was more likely to be well differentiated (85% grade 1) than in those cases without metaplasia (68% grade 2 or above). These differences did not achieve statistical significance ($p = 0.06$). The presence or absence of metaplasia did not correlate with the depth of invasion of the carcinoma into the myometrium. Although a "pushing" margin was seen more often when cancer and metaplasia coexisted and an "infiltrative" pattern was more typical of cancer alone, the correlation was not of statistical significance.

Patients with only metaplasia were significantly younger (57 ± 2.1 years) than patients with metaplasia and cancer (60 ± 1.3 years) or patients with cancer only (65 ± 2.1 years) ($p = 0.04$).

Table VI shows the associated nonneoplastic diagnoses when only metaplasia was seen in the endometrial curretings. The finding of some "normal" endometrium was significantly correlated with the absence of carcinoma ($p = 0.01$).

Neither a lymphocytic stromal infiltrate nor stromal foam cells correlated with the finding of carcinoma in the curettings. A desmoplastic response in the curettings was likely to be associated with cancer and was noted in only one of the 11 cases of "pure" metaplasia. The correlation of desmoplastic reaction and cancer did not, however, achieve statistical significance ($p = 0.06$).

Table III. The relationship of metaplasia and histologic type of carcinoma diagnosed in endometrial biopsy/curettage specimens

Histologic type	*Cancer without metaplasia*	*Cancer with metaplasia*	*Total*
Endometrioid	17	11	28
Adenosquamous	2	0	2
Clear cell	2	0	2
Papillary serous	4	0	4
"True mixed"	6	4	10
Other	1	0	1
Total	32	15	47

There were nine deaths caused by cancer in the study group of 60 women. Only two of these occurred in patients with both metaplasia and carcinoma. None of the patients with only metaplasia in the curettings had carcinoma of the uterus, and none of these women had a recurrence or died of endometrial carcinoma. The life-table survival for all women with cancer (with or without metaplasia) was 81% ± 5.8%. The corresponding figure for those with cancer and metaplasia was 91% ± 6.2% while those with cancer and no metaplasia had a 70% ± 10.8% survival prediction. These differences do not achieve statistical significance ($p = 0.09$).

Comment

The endometrial metaplasias were thoroughly described by Hendrickson and Kempson[4] in 1980 but there have been only a few subsequent discussions.[6-8] The cases reported by them were, however, specifically selected to exclude carcinoma. We believe this has led some to conclude that the diagnosis of metaplasia precludes the possibility of a coexisting carcinoma of the endometrium, especially a carcinoma which could invade the myometrium.[1,9] The present series emphasizes that metaplasias coexist in endometria with either endometrial hyperplasia or carcinoma.

Our experience with FIGO Stage I carcinoma indicates that metaplasia often coexists with carcinoma: 32% (15/47) in uterine curettings and 38% (15/40) in the hysterectomy material. Metaplasia was seen almost as often as hyperplasia with cancer. Although the association of squamous metaplasia and well-differentiated adenocarcinoma has been described for decades (for example, adenoacanthoma), the coexis-

Table IV. Types of metaplasia encountered in endometrial biopsy/curettage specimens*

tence of a variety of non-squamous metaplasias and adenocarcinoma has not heretofore been stressed. In our series the most common metaplasia coexisting with cancer was eosinophilic, not squamous, metaplasia.

Silverberg[1] views endometrial metaplasia as having only "dubious distinction," important only in that they not be mistaken for carcinoma. We believe that the separation of benign metaplastic changes from malignancy continues to be a critical problem. Thirteen of 60 patients (22%) who were originally diagnosed and treated as having cancer were felt to have only metaplasia and hyperplasia by current criteria. Including such patients in a therapeutic trial could lead to erroneous conclusions regarding the therapeutic outcomes.

Distinguishing metaplasias from carcinoma admittedly can be difficult. Pattern diagnosis alone is unreliable. Careful attention to the cytologic detail and awareness of the architecture of metaplasias permit their recognition. Other histologic variables were investigated for their utility in differentiating metaplasia from carcinoma, but only the presence of normal endometrium admixed with metaplasia reached statistical significance. Observed trends, however, suggested that the presence of a demoplastic response and scant or absent normal endometrium in the curettings often suggested the coexistence of cancer with metaplasia.

The clinical setting of metaplasia, with or without associated carcinoma, closely parallels that of endometrial hyperplasia. Metaplasia and hyperplasia tend to occur in relatively younger women with abnormal uterine bleeding. Chronic oligoovulation, exogenous estrogen usage, exogenous obesity, and intrauterine contraceptive device usage have all been reported to be associated with metaplasia,[4,6-8] but our data were not coded to correlate these features.

In this series, when metaplasia or hyperplasia was

associated with carcinoma, the malignancies were mostly well differentiated and were more often of the endometrioid variety. There were no instances in either the curettage material or in the hysterectomy specimens where metaplasia seemed to merge into or to be transformed into carcinoma, in spite of careful histologic review.

In our study, we had no case in which cancer was absent in the curettings but present in the hysterectomy specimen. Since completion of this review, however, we have had two patients in whom there was only nonsquamous metaplasia in the formal curettings but in whom metaplasia and carcinoma were found in the removed uterus. In both patients the carcinoma was well differentiated but invaded the myometrium, in one case more than 50% of the wall thickness.

In conclusion, metaplastic proliferations are important not only because of the need to be differentiated from adenocarcinoma but because they can be found in association with carcinoma. This association is far more rich and varied than just the familiar adenoacanthoma and both the pathologist and the clinician must be aware of the potential coexistence. If metaplasia is diagnosed in the setting of perimenopausal or postmenopausal bleeding by office endometrial biopsy or curettage, a more complete sampling (formal curettage) should be considered. Because of the coexistence of metaplasia and adenocarcinoma found in this retrospective review, we feel that the endometrial metaplasias should be viewed with concern.

Discussion

DR. MICHAEL P. BORN, Miami, Florida (Official Guest). Endometrial metaplasia has been defined as the replacement of the endometrial glandular epithelium by an epithelium that is normally found in another müllerian-derived organ such as the fallopian tube.[1] Dr. Taylor and his colleagues asked the question, "Do the identification and segregation of these metaplastic changes have any real importance or do they only add further confusion?" The question is answered in the article's conclusion where it is asserted that the metaplasias are important because they may be confused with carcinomas and because they frequently coexist with carcinomas. Others have acknowledged these points separately[2-4] but have not highlighted their combined significance as have Dr. Taylor and his coauthors. If these conclusions are warranted, they provide ample justification for clinicians and pathologists alike to be aware of the existence and significance of the endometrial metaplasias.

The data for this paper were generated by the review of curettage and hysterectomy specimens for 60 patients treated for FIGO Stage I endometrial carcinoma at the University of Virginia Medical Center between 1969 and 1979. This review identified 13 patients who did not have carcinoma. Eleven of these 13 patients had metaplasia that presumably led to the misdiagnosis. In addition, a high frequency of coexistence of metaplasia and carcinoma was identified. The incidence of coexistence was 32% in the curettage specimens and 37.5% in the hysterectomy specimens. Certainly these data should disabuse us of any misconception that the presence of metaplasia precludes the presence of carcinoma.

The authors made additional important observations. They noted that metaplasias and hyperplasias are found in similar clinical settings, particularly that of the younger patient with abnormal uterine bleeding. Although not documented in this study, other investigators believe that metaplasias are stimulated by unopposed estrogen, both endogenous and exogenous.[3,5] Another observation of clinical interest is that the endometrial carcinomas found with coexistent metaplasia are usually well differentiated and usually of the endometrioid cell type; these patients generally have an improved 5-year survival rate when compared with that for carcinomas without metaplasia. This study was obviously retrospective. I would like to ask Dr. Taylor if he is collecting any prospective data and, if so, whether estrogen and progesterone receptors are being determined.

The 13 cases that were initially misdiagnosed, or perhaps overdiagnosed, represent 21% of the study group. This would seem a startling statistic until we recognize it as merely illustrative of the continuing difficulty pathologists have in agreeing on a classification for the proliferative endometrial lesions. In a review of 100 consecutive cases of endometrial hyperplasia referred to the Sloane Hospital for Women, 69% of the diagnoses were downgraded by the reviewers.[4] Debate con-

tinues about the existence and significance of endometrial carcinoma in situ as well as the diagnostic criteria for well-differentiated endometrial carcinoma.[6-9] In this environment of academic uncertainty, clinicians must communicate freely with their pathologists to be sure that the biologic potential of the endometrium is understood and that subsequent management is appropriate.

Hendrickson and Kempson[3] made an important distinction between metaplasias that are found in otherwise unremarkable, nonhyperplastic endometrium and metaplasias found in the midst of atypical hyperplasias, which they called "metaplastic hyperplasias." The first group should pose no problem of interpretation for the pathologist and should be considered neither malignant nor premalignant. On the other hand, the "metaplastic hyperplasias" may well present a very complex histologic picture subject to overdiagnosis. These authors believe that these "metaplastic hyperplasias" represent a subset of atypical adenomatous hyperplasias and share the generally accepted increased risk of subsequent development of adenocarcinoma. Perhaps the pivotal point is not the presence of metaplasias but rather the "company they keep."

The two cases that occurred after the review was completed raise some interesting issues. These patients are reported to have "only metaplasia" in the curettings but metaplasia and carcinoma in the hysterectomy specimens. Of greater concern is that in both cases the myometrium was invaded. I would like to pose several questions regarding these cases. If only metaplasia was diagnosed on the curettings, what were the indications for hysterectomy? Was there atypical hyperplasia in the curettings as well? Is there any theory as to why the carcinomas were missed at curettage? Finally, how can we clinicians avoid similar pitfalls?

The authors' conclusions are that the metaplasias are important because they may be misdiagnosed as adenocarcinoma and because they may be frequently associated with carcinoma. In closing, I would like to ask Dr. Taylor two final questions. First, does he accept the concept of the "metaplastic hyperplasias" and their categorization as a subset of the atypical hyperplasias, imbued with their asssociated implications? Second, would he agree that, although a potential source of confusion, the true significance of the metaplasias does not lie in their presence alone but rather is dictated by the background endometrium, whether it be atrophic, proliferative, hyperplastic, or malignant?

DISCUSSER NO. 2. I have a great deal of respect for the quality of pathologic diagnosis at the University of Virginia and so I question whether these interpretations would occur with that quality. This is more likely to occur in our community hospitals. One of the concerns that oncologists have had is that there is a lack of respect on the part of many of us for the lethality of endometrial carcinoma. It is considered a malignancy that is readily curable. From your data, then, looking back from 1980, would it be fair to say that we should deduct from the cure rate of endometrial carcinoma some 15% to 20% that would indicate that it is indeed a more lethal disease than we have regarded it?

DR. TAYLOR (Closing). Misinterpretation of pathologic results is a serious problem. It is particularly a problem from the point of clinical trials. A large number of patients do not have very aggressive lesions however these proliferative changes are described, so for prospective trials it is very difficult to interpret the outcome. That does automatically shift survival downward. If the series is weighted with 20% very favorable lesions, the survival rate for endometrial cancer is lowered and the results do not look good. Do I accept metaplastic hyperplasias as a concept and are they judged by the "company they keep"? I think all 13 of these patients had hyperplasia. Eleven of those had metaplasia and hyperplasia. I am sorry that I did not make it clear that this is part of the "company they keep." I think what makes it so confusing is the architectural complexity of hyperplasia superimposed on metaplasia. These are very complex lesions. The examples of metaplasia with chronic infections and with intrauterine contraceptive device usage indicate that they are just a histologic response. So I would say yes, my interpretation is that they are judged by the "company they keep." Do I accept it as a concept? I think it is real, that hyperplasias do exist with metaplastic changes, but this concept is different from the hyperplasias seen with chronic infections and in younger people. As far as the two patients that I mentioned after the conclusion of the study and the indications for hysterectomy, one of them actually caused us to initiate the study, to see how often we had confused metaplasia with carcinoma or how often we had misdiagnosed it. This was an asymptomatic woman who had an endometrial biopsy specimen with ciliated and eosinophilic metaplasia. A curettage produced the same results, and the hysterectomy specimen showed a well-differentiated invasive adenocarcinoma. However, there was no real hyperplasia in the

biopsy specimen or the curettings. The second patient had hyperplasia with a great deal of metaplastic change, and metaplasia was the dominating feature that caught our attention. The lesion was designated as hyperplasia and metaplasia, then an invasive lesion was found at hysterectomy. I do not really have a good theory as to why we missed these lesions. We have looked back at the material, of course, in great detail, and on review the diagnosis was confirmed. The pitfalls, I think, are intellectual ones in that we believe that metaplasias in this age group and in this clinical setting are harmless. One of the articles we referred to said that metaplasias are of absolutely no clinical significance unless they are a source of confusion for the unwary pathologist. I think that even wary pathologists can be confused by this area, which is not so simple. I think it may be simple to talk about but hard to recognize. To me that is the pitfall. As far as prospective data, no we do not have that information. We have just completed this review of all of our cases of endometrial cancer. We are trying to plot out the future and we have not finished sorting the past or organizing it.

Conservative surgical management of isthmic ectopic pregnancies

Harriet O. Smith, M.D., Andrew A. Toledo, M.D., and John D. Thompson, M.D.
Atlanta, Georgia

During the 12-month study interval ending March 30, 1986, there were 203 ectopic pregnancies at Grady Memorial Hospital, a ratio of one ectopic gestation per 34 deliveries. Twenty patients with isthmic ectopic pregnancies were selected for treatment by one of three operative modalities. Seven patients with ruptured isthmic ectopic pregnancies underwent segmental tubal resection without reanastomosis. All four patients who underwent segmental tubal resection with primary microsurgical reanastomosis had postoperative hysterosalpingograms demonstrating bilateral tubal patency. One pregnancy has occurred in this group. Nine patients underwent linear salpingostomy. In five of the six patients who had postoperative hysterosalpingography, patency of the involved fallopian tube was demonstrated. Four of these nine patients, including one patient with contralateral tubal occlusion, have conceived. We conclude that linear salpingostomy for isthmic ectopic pregnancies is as effective as segmental tubal resection with primary microsurgical reanastomosis in achieving tubal patency. (Am J Obstet Gynecol 1987;157:604-10.)

Key words: Isthmic ectopic pregnancies. linear salpingostomy, primary microsurgical reanastomosis

Linear salpingostomy has recently become the surgical treatment of choice in the management of ampullary or infundibular ectopic pregnancies, especially when future fertility is desired.[1-5] However, the optimum surgical approach to isthmic ectopic pregnancies remains controversial. Three conservative operations have been described: (1) segmental resection of the involved portion of fallopian tube and reanastomosis at a later operation, (2) segmental resection and primary microsurgical reanastomosis, and (3) linear salpingostomy.[1-9]

From the Department of Gynecology and Obstetrics, Emory University School of Medicine.
Presented by invitation at the Forty-ninth Annual Meeting of The South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 25-28, 1987.
Reprint requests: Harriet O. Smith, M.D., Department of Gynecology and Obstetrics, Emory University and Affiliated Hospitals, 69 Butler St., S.E., Atlanta, GA 30303.

Segmental resection with microsurgical reanastomosis at a later operation is the most favored technique.[5-8] Objections to primary reanastomosis include the technical difficulties in performing reanastomoses at an untimely hour, the variable skills of the surgeons involved in performing microsurgery, the additional operating time required, and the difficulty in assessing patency of the other fallopian tube during operation. However, excision of the isthmic ectopic pregnancy and primary reanastomosis without the aid of the operating microscope or loupes have been described by Stangel et al.[9] They have successfully performed this operation on seven patients, two of whom later had intrauterine pregnancies.[7, 9]

Linear salpingostomy for isthmic ectopic pregnancies is seldom described in the literature and is generally disfavored.[5-8] The narrow isthmic lumen may be particularly susceptible to ectopic implantation if lin-

ear salpingostomy results in additional scar formation within the fallopian tube. In a recent report, DeCherney and Boyers[8] concluded that simple linear salpingostomy without resection of the damaged portion of fallopian tube usually resulted in tubal obstruction.

The purpose of this study was to compare the success of linear salpingostomy with the success of segmental resection followed by primary intraoperative reanastomosis in achieving tubal patency.

Material and methods

Criteria for enrollment in the study included: (1) a preoperative diagnosis of ectopic pregnancy, suggested by an abnormal rise in quantitative determinations of human chorionic gonadotropin, ultrasound, and/or culdocentesis; (2) stable vital signs and hematocrit; (3) expressed desire by the patient for future fertility; and (4) intraoperative identification of an isthmic ectopic pregnancy. Informed consent was obtained before operation. When patients were found intraoperatively to have unruptured isthmic ectopic pregnancies, the involved fallopian tubes were alternately treated by linear salpingostomy or by segmental resection with primary microsurgical reanastomosis. In other words, unless a tubal microsurgeon was unavailable during the laparotomy, every other patient found to have an unruptured isthmic ectopic pregnancy underwent segmental resection followed by primary microsurgical reanastomosis, and the procedure to be performed was determined preoperatively. Patients found intraoperatively to have ruptured isthmic ectopic pregnancies were managed by segmental resection of the involved portion of the fallopian tube. Depending on the results of postoperative hysterosalpingography, these patients were candidates for reanastomosis at a second operation.

Segmental resection and primary reanastomosis were performed by a technique similar to that described by Stangel et al.,[9] with the exceptions that the operating microscope and loupes were used and reanastomosis was performed in two layers. A small Babcock clamp was placed on either side of the ectopic gestation to elevate and stabilize the fallopian tube. A 6-0 delayed absorbable suture was placed in the mesosalpinx directly beneath the ectopic gestation. The segment of fallopian tube containing the ectopic gestation was excised, and the suture was tied. The cervix was then occluded with a Buxton clamp and transfundal chromotubation was performed to document patency of the proximal portion of the fallopian tube. Retrograde chromotubation was performed to confirm patency of the distal segment of the fallopian tube. Microcautery was used to control small bleeding vessels and lactated Ringer's solution was used for continuous irrigation.[10]

Table I. Ectopic pregnancies at Grady Memorial Hospital between April 1, 1985, and March 30, 1986

	Range	*No.*	*%*	*Mean*
Age	15-39	202		25.7
15-19		17	8.4	
20-29		144	71.3	
30-39		41	20.3	
Parity	0-5	200*		
0		60	30.0	
1		77	38.5	
>1		63	31.5	
Gravidity	1-7	200*		
1		25	12.5	
>1		175	87.5	

*Gravidity and parity are unknown for two patients.

Microsurgical tubal reanastomosis was performed with interrupted 8-0 nylon suture in two layers.

Linear salpingostomy was performed in the same manner as described by others.[2-6] A linear incision was made along the antimesenteric border of the fallopian tube with the pinpoint tip of the Bovie electrocautery unit, and the ectopic pregnancy was gently delivered through this incision, with care taken to remove most of the trophoblastic tissue without denuding the placental bed and causing unnecessary bleeding. Hemostatis was achieved by using the bipolar electrocautery unit. The linear incision was left open.

Regardless of the operation performed, the pelvic cavity was thoroughly irrigated with lactated Ringer's solution. When laparotomy pads were necessary for exposure, they were moistened and placed in sterile plastic bags to avoid damage to serosal surfaces. Perioperative antibiotic prophylaxis was used routinely. Approximatley 200 ml of dextran 70 was placed into the peritoneal cavity before closure.[2] Postoperative hydrotubation was not performed, since its benefits have not been substantiated.[11] Hysterosalpingography was performed approximately 3 months after operation to evaluate tubal patency.

Results

The diagnosis of ectopic pregnancy was confirmed by laparotomy or laparoscopy in 202 patients at Grady Memorial Hospital during the 12-month study interval ending March 30, 1986. Grady Memorial Hospital serves the indigent patients of metropolitan Atlanta, Georgia. There were 6802 deliveries during that interval. Thus the incidence of ectopic pregnancies was 1:34 deliveries. This is the highest incidence of ectopic pregnancy reported in the American literature.

The ages of these patients ranged from 15 to 39, and the mean age was 25.7. The vast majority of patients were between 20 and 29 years of age (Table I). Parity

†Fimbrioplasty performed intraoperatively, following which the tube was patent.

ranged from 0 to 5, and the mean parity was 1.2. The importance of future fertility for these patients is exemplified by the fact that 136 of these patients (68.5%) had one or no living children, and 60 patients (30%) were nulliparous. During their hospitalizations, 125 patients (62%) expressed a desire for future fertility and preferred tubal conservation if this could be done safely.

The ectopic pregnancy was located in the ampullary or infundibular portion of the fallopian tube in 140 patients (69%), in the isthmicoampullary portion in six patients (0.3%), in the isthmic portion in 40 patients (19.7%), and in the interstitial portion in 15 patients (7.4%) (Table II). One ovarian pregnancy and one abdominal pregnancy occurred. Among the 202 patients, there were 203 ectopic gestations; one patient was found to have bilateral tubal pregnancies. The incidence of repeat ectopic pregnancy for these patients was 7.4% (15 patients); two patients had repeat ectopic pregnancies within the study interval.

Twenty patients with isthmic ectopic pregnancies were enrolled in the study. They were divided into three groups: Group 1, patients with unruptured isthmic ectopic pregnancies managed by segmental resection and primary microsurgical reanastomosis; Group 2, patients with unruptured isthmic ectopic pregnancies managed by linear salpingostomy; Group 3, patients with ruptured isthmic ectopic pregnancies managed by segmental resection without reanastomosis.

Group 1 (Table III) consists of four patients with unruptured isthmic ectopic pregnancies who underwent segmental tubal resection and primary microsurgical tubal reanastomosis. Although three of these patients appeared to have tubal occlusion of the other fallopian tube by intraoperative transfundal chromotubation, postoperative hysterosalpingography demonstrated bilateral tubal patency. One of these patients now has an intrauterine pregnancy documented by ultrasound, and two are actively using contraception.

Group 2 (Table IV) consists of nine patients who underwent linear salgingostomy for unruptured isthmic ectopic pregnancies. The last three patients in this group underwent linear salpingostomy because a microsurgeon was not available at the time of laparotomy. Hysterosalpingography were performed in six of these patients, and five had patency of the involved fallopian tube. The remaining patient had a hydrosalpinx on the involved side, although the isthmic portion was patent. Four of these nine patients currently have intrauterine pregnancies documented by ultrasound or have already been delivered of their infants. One of these four pa-

*Documented by ultrasound.
†Fimbrioplasty performed intraoperatively, following which the tube was patent.

tients, S. Y., demonstrated patency of the involved fallopian tube, but the opposite tube was occluded. Linear salpingostomy for this patient resulted in tubal patency followed by a successful intrauterine pregnancy. Two of these four patients have not had follow-up hysterosalpingography because they became pregnant before the procedure could be performed, and the remaining patient had bilateral tubal patency. The other five patients in this group are actively using contraception.

Group 3 (Table V) consists of seven patients who had ruptured isthmic ectopic pregnancies. Each of these patients were treated by segmental resection of the involved segment without primary reanastomosis. Four of these patients had postoperative hysterosalpingography that demonstrated patency of the opposite fallopian tube and, as expected, occlusion of the involved tube. Interestingly, one of these patients appeared to have an occluded opposite fallopian tube by intraoperative chromotubation. There are two pregnancies in this group, both occurring before hysterosalpingography could be performed.

Comment

The incidence of ectopic pregnancy is increasing.[12-14] An unpublished study at Grady Memorial Hospital in Atlanta revealed that the incidence of ectopic pregnancies between July 1, 1983, and March 30, 1985, was an alarming 1:44 deliveries (McSwain HF, Mitchell DE. Unpublished data). The subsequent year, the incidence of ectopic pregnancy at Grady Memorial Hospital was 1:34 deliveries, a 29% increase in the inci-

dence of ectopic pregnancies in a single year. The incidence of ectopic pregnancies per total pregnancies (deliveries and abortions) was subsequently compared. In spite of the rising number of abortions, a 27% increase in the incidence of ectopic pregnancies per total pregnancies was found.

After tubal pregnancy, 60% to 70% of patients are infertile.[14] In this series, 30% were nulliparous, and more than 60% wanted another child. Conservative operations with preservation of the fallopian tube are especially designed for the nulliparous woman and the patient with a history of infertility, for whom the removal of the involved fallopian tube may result in permanent sterility.

Isthmic ectopic pregnancies are uncommon, ranging from 5% to 15%[8] of all ectopic pregnancies. The percent of isthmic ectopic pregnancies at Grady Memorial Hospital in the past 12 months was 19.7. Because isthmic gestations are less common, it is almost impossible for anyone to determine the most feasible surgical approach. The high incidence of ectopic pregnancies at Grady Memorial Hospital made possible a comparison of these operative techniques, but even this series is small.

Linear salpingostomy has been successful in maintaining reproductive function in patients with ampullary ectopic pregnancies, possibly because the trophoblastic proliferation occurs mainly beneath the tubal mucosa.[15] This study indicates that linear salpingostomy may be successfully used for isthmic ectopic pregnancies, as well. Because isthmic ectopic pregnancies rupture at an earlier gestational age than ampullary ectopic pregnancies, the diagnosis must be made at the earliest possible time in order for a conservative operation to be performed. A high index of suspicion must be maintained. When the diagnosis of ectopic pregnancy is suspected, culdocentesis, serial quantitative human chorionic gonadotropin, ultrasonography, and diagnostic laparoscopy may confirm the diagnosis before irreparable tubal damage has occurred.

Stangel et al.[7, 9] have previously demonstrated that primary microsurgical reanastomosis after isthmic ectopic resection results in tubal patency and subsequent fertility. We have demonstrated that linear salpingostomy also results in tubal patency for isthmic ectopic gestations.

Is primary microsurgical reanastomosis necessary if the uninvolved fallopian tube is patent? Although reanastomosis has been performed in some series when the other fallopian tube was patent by hysterosalpingography, a controlled study is needed to determine if this procedure is indicated. In this series, intraoperative chromotubation was inconclusive in evaluating patency of the other fallopian tube. Intraoperative microsurgical reanastomosis may eliminate the need for a second operation.

Primary microsurgical reanastomosis requires the presence of a gynecologist with microsurgical capabilities. Linear salpingostomy may be performed successfully by any gynecologist who follows the basic operative principles practiced by most microsurgeons. In this series, linear salpingostomy, a conservative operation usually reserved for ampullary ectopic pregnancies, was as effective as primary microsurgical reanastomosis in achieving tubal patency.

Discussion

Dr. R. Montague Laffitte, Jr., Greenville, South Carolina (Official Guest). Over the last 20 years, there has been an increase in the incidence of tubal gestation. This is probably associated with the increase in the incidence of pelvic inflammatory disease, the use

of intrauterine contraceptive devices, and the increase of reconstructive tubal surgery. Early and aggressive antibiotic therapy for pelvic infections may also play a role by preventing complete occlusion of diseased tubes. During this same time, new and improved diagnostic tools (β-subunit of human chorionic gonadotropin, ultrasonography, laparoscopy), have led to earlier diagnosis of tubal pregnancy. This earlier diagnosis permits the use of conservative surgery in the treatment of this condition.

Conservative surgery should be considered in any woman who has a tubal pregnancy and who wishes to conserve her fertility, even in those cases with a normal contralateral tube. We have come a long way since Tait[1] described salpingectomy as definitive treatment for ruptured tubal pregnancies in 1884. In 1953, Stromme[2] became the first to describe a conservative approach to tubal pregnancy by performing a salpingostomy. Since then, many authors have reported on segmental excision of tubal pregnancies with or without anastomosis. More recently, Gomel,[3] DeCherney et al.,[4] and others have been strong advocates of the use of laparoscopy in the conservative treatment of this condition. Most authors conclude that there is no difference in the subsequent extrauterine pregnancy rates, whether the patients are treated conservatively or radically for the initial ectopic pregnancy, but there does seem to be an increase in subsequent viable pregnancy rates in those treated conservatively.

The study of Smith et al. has used a very well-defined subset of patients to compare the effectiveness of linear salpingostomy and segmental tubal resection with primary microsurgical reanastomosis in the conservative treatment of tubal pregnancy. Because of the low incidence of isthmic ectopic pregnancies, the numbers are small (N = 20).

Four patients with unruptured isthmic pregnancies underwent tubal resection and primary microsurgical reanastomosis. Postoperative hysterosalpingography demonstrated bilateral tubal patency. One of two patients has achieved an intrauterine pregnancy (two are actively using contraception). Stangel and Gomel[5] used this procedure in seven patients with isthmic pregnancy. The oviducts remained patent after operation in all seven. Two patients have become pregnant and were delivered uneventfully. In these two patients, the reconstructed tube was the only functional tube.

The second group of patients (N = 9) had unruptured isthmic ectopic pregnancies managed by linear salpingostomy, the technique that has been used quite successfully by DeCherney et al.[6] and others in the management of ampullary ectopic pregnancies. Five of six patients had patent tubes after operation. Two became pregnant before hysterosalpingography could be performed. Four of these nine have had documented intrauterine pregnancies. These numbers are more promising than the ones reported by DeCherney and Boyer[7] in 1985. In their study of 10 patients with isthmic ectopic pregnancies, the four treated by linear salpingostomy have not conceived. Hysterosalpingography demonstrated tubal occlusion in three of these four patients.

The third group consisted of seven patients with ruptured isthmic ectopic pregnancies treated by segmental resection without primary reanastomosis. Four of these patients had postoperative hysterosalpingography that revealed the opposite tube to be patent. Three of these four patients are now using contraception. Two of the seven patients have had intrauterine pregnancies (neither of these patients had postoperative hysterosalpingography).

From Dr. Smith's data and a review of the literature, it seems that segmental resection with either immediate or delayed anastomosis appears preferable to linear salpingostomy in the conservative management of unruptured isthmic pregnancies. Considering the anatomy of the fallopian tube, this is not surprising. The isthmus contains the narrowest lumen and the thickest musculature. Budowick et al.[8] have shown that the growing gestation rapidly penetrates the wall of the tube with the trophoblast destroying the surrounding muscularis. Segmental resection removes the damaged isthmus and the thick muscularis and simple endothelium facilitates anastomosis. Linear salpingostomy without resection of the damaged portion would seemingly result in isthmic obstruction.

In conclusion, conservative operation for ectopic pregnancies should be considered in any patient desiring to preserve her fertility. Early diagnosis is imperative; patients who have an unruptured tubal gestation and who are surgically stable are the best candidates for conservative therapy. Linear salpingostomy or tubal abortions seem to be the treatment of choice for ampullary ectopic pregnancies. Segmental resection, with or without anastomosis, seems to be the treatment of choice for isthmic ectopic pregnancies. However, Dr. Smith has shown that linear salpingostomy is effective in the treatment of isthmic ectopic pregnancies. The data are encouraging, and it would be interesting to look at these numbers again in 1 to 2 years and compare the results. Linear salpingostomy does offer several advantages. For the gynecologist with little or no training in microsurgery it is technically easier, and for this same physician it undoubtedly decreases operative time. One thing not mentioned but that must be considered by all gynecologists performing conservative operations is the problem with delayed hemorrhage. This can be secondary to persistent growth of gestational tissue. It has been recommended by Rivlin[9] that routine serial tests of the level of the β-subunit of human chorionic gonadotropin be done in the postoperative period.

Dr. Lynn Gordon Borchert, Greenville, North Carolina. Dr. Smith, in my personal experience in dealing with unruptured ectopic pregnancy, I have used the microsurgical technique for linear salpingostomy in these patients and apparently in your series macrosurgical procedures were used exclusively. Has there been any study in your program comparing microsurgical linear salpingostomy to macrosurgical procedure in an attempt to identify potential bleeding sites and to coagulate them and occlude them before beginning the linear salpingostomy procedure? Along those lines what has been the interoperative morbidity of your patients who have had linear salpingostomy relative to blood replacement and hemorrhage?

Dr. Jaroslav F. Hulka, Chapel Hill, North Carolina. I have not a question but a comment. In this era of in vitro fertilization it becomes quite important to try to document the success of all sorts of fertility surgery as opposed to the 10% to perhaps 20% success of in vitro fertilization. Dr. Smith and colleagues are to be congratulated on beginning this in this rare problem and I hope they will continue to find some operations that will still be required or recommended rather than assuming that patients with these disasters should be automatically undergoing in vitro fertilization.

Dr. Smith (Closing). No one at our institution has attempted to use microsurgical techniques solely for linear salpingostomies. I have used loupes in performing this procedure. I have personally found that when I use the pinpoint tip of the Bovie instrument on low power I am coagulating most of the vessels. I personally have had a great deal of difficulty with engorged tubes in being able to obtain hemostasis with the bipolar cautery or microcautery. Several people at our institution, instead of using the pinpoint Bovie, were using a No. 15 blade or microscissors and they experienced more trouble bleeding than I have personally experienced when scrubbing with residents who were having to do a resection because of this. Those who required transfusion did not have either a microsurgical reanastomosis or a linear salpingostomy. It was felt that the condition of these patients was unstable and the most rapid technique should be performed. I did not include this in the article just to shorten its length, but we did look at operative times for each procedure. It is interesting to note than an average of only about 35 minutes more was required to do a microsurgical reanastomosis than a linear salpingostomy. A great deal of time should be taken to methodically make sure that the bleeding is controlled, so additional operating time is not really a contraindication to microsurgical reanastomosis.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Simultaneous objective and subjective evaluation of meclofenamate sodium in the treatment of primary dysmenorrhea

Roger P. Smith, M.D., and J. Roger Powell, M.D.
Augusta, Georgia, and Urbana, Illinois

Eighteen patients participated in a double-blind, placebo-controlled, single-dose, crossover study of meclofenamate sodium in women with primary dysmenorrhea. Simultaneous evaluations of pain intensity and pain relief, sampling of continuous intrauterine pressure recording, and monitoring of blood meclofenamate levels were carried out. Improvements in pain intensity and pain relief were observed at 45 minutes and reached statistical significance at and beyond 1 hour 45 minutes after meclofenamate therapy. Ten of 14 uterine pressure parameters showed statistically significant responses after drug therapy and 12 of the 14 parameters showed statistically significant differences in time-response patterns. Statistically significant changes were noted as early as 45 minutes after meclofenamate therapy. Statistically significant correlations were found between and among the parameters of blood drug level and the subjective and objective measures. No drug-related adverse effects were found. (Am J Obstet Gynecol 1987;157:611-8.)

Key words: Dysmenorrhea, dysmenorrhea therapy, intrauterine pressure, meclofenamate, blood drug levels

Many studies have reported symptom improvement in patients with primary dysmenorrhea treated with nonsteroidal anti-inflammatory drugs. While success of treatment has been reported to vary from a low of 64%[1] to more than 95%,[2] results are affected by large variations in the data and relatively high placebo response rates found with pain evaluation. Unfortunately, only a small number of objective studies have been published, and these report on small study groups that vary from 3 to 13 patients.[3,4] None have combined the methodology of subjective assessment techniques with the rigor of objective measurements. Furthermore, to our knowledge, no study has attempted to correlate uterine activity with pain severity and each with blood drug level. To further understand the association of pain, intrauterine pressure, and plasma drug levels in patients with primary dysmenorrhea, the following investigation with meclofenamate sodium (Meclomen) was undertaken.

Material and methods

A double-blind, placebo-controlled, single-dose, crossover study of subjective and objective responses to meclofenamate was undertaken in 18 patients with primary dysmenorrhea. Diagnosis was established on the basis of clinical history and physical examination. In addition, patients were required to have either a positive total score on a menstrual symptom questionnaire (which has been used in previous studies[4,5] and described elsewhere[6]) or to have had sufficient response to previous treatment with a nonsteroidal anti-inflammatory drug to have continued therapy. All patients had regular menstrual cycles, dysmenorrhea for more than 6 months' duration, and consistently moderate to severe symptoms without treatment. None of the patients were using oral contraceptives or an intrauterine contraceptive device or had contraindications to the use of nonsteroidal anti-inflammatory drugs. All patients were informed regarding the nature, procedures, and requirements of the study. Informed consent was obtained before entry into the study.

The study was conducted during two menstrual cycles, one while the patient received 200 mg of meclofenamate and one during administration of placebo, with the sequence determined by double-blind randomization. Each patient was asked to report to the clinic for study within 24 to 36 hours of the onset of menstrual flow and to take no medication within 6 hours of the study time. At the time of study, a catheter-tip microtransducer (Millar PC771) was placed

Table I. Data schedule

Monitoring dose	*Baseline**	*Time after treatment (min)*

Plasma drug level	X	X	X	X		X		X	

*Within 30 minutes before treatment; intrauterine pressure averaged over two 15-minute segments.
†Pressure recording for 15-minute segment ending at time interval.

to allow recording of intrauterine and endocervical pressures. Placement and recording were done according to previously reported methods.[7] A 21-gauge heparin lock was placed for blood sampling. A minimum of 30 minutes of baseline pressure recording was obtained, baseline subjective pain intensity was recorded, and a control blood sample was collected. The double-blind study medication was then administered.

Intrauterine pressure was continuously recorded for 3 hours 15 minutes after drug administration. Subjective and objective assessments and blood samples were obtained as shown in Table I.

Subjective analysis. Pain intensity was recorded as 0 = none, 1 = mild, 2 = moderate, or 3 = severe. Pain relief was recorded as 0 = none, 1 = a little, 2 = some, 3 = a lot, or 4 = complete.

Pressure analysis. Each pressure recording strip was divided into 15-minute segments for analysis. The two 15-minute segments preceding medication were averaged to provide baseline measurements. Response to medication was evaluated for the 15-minute segments ending as shown in Table I. Pressure recordings for each segment were converted into digital information and processed by microcomputer by means of a previously reported technique and algorithm.[7,8]

Computer analysis yielded 14 manometry parameters. For purposes of clinical evaluation, the parameters were categorized into general descriptive measures (average pressure, total area under the pressure curve, maximum rate of pressure increase, maximum rate of pressure decrease, number of pressure sign [slope] changes), measures of uterine work (maximum pressure, average peak pressure, number of peaks [contractions], contraction work, linear displacement), and measures of uterine rest (baseline pressure, baseline area under the pressure curve, percent time at baseline, and minimum pressure).

These parameters have been found to yield consistent and reliable characterizations of the pressure records.[7,8]

Meclofenamate blood level analysis. Plasma samples were analyzed at Warner-Lambert/Parke-Davis Pharmaceutical Research Division by means of a highly linear, specific, and stable high-power liquid chromatography assay.[9] The minimum detectable concentration of meclofenamate is 0.03 μg/ml.

Statistical methods. Two overall measures of pain were calculated for each subject at each cycle: the total of the pain relief scores (TOTPAR) and the sum of the pain intensity difference scores (SPID). TOTPAR and SPID were evaluated by a crossover analysis of variance that tested for treatment (drug) differences. In addition, the pain relief and pain intensity difference scores were analyzed by a crossover analysis of variance at each study time. The overall frequency of pain relief and pain intensity scores were tabulated and a χ^2 test was used to detect treatment differences.

Manometry parameters were analyzed for each subject at each cycle with the average of the pretreatment values used as the baseline response. The percentage of change from baseline was calculated for each of the eight posttreatment study times by the formula:

$$\frac{(\text{posttreatment response} - \text{baseline response})}{\text{baseline reponse}} \times 100$$

Comparability of baseline values across treatment groups for each manometry parameter were tested by a crossover analysis of variance. Percentage of change from baseline for each manometry parameter was evaluated using the analysis of variance for the two-period repeated measurements crossover design.* The fixed sources of variation were the period effects (cycle), direct treatment effects (drug), study time, and the interaction of study time with period and treatment. Three error terms were used to test the fixed effects of period and treatment, study time, and interaction.

The effects of interest were the treatment effect (difference between drug and placebo in the levels of the time-response curves), the period effects (difference in the order of treatments), and the interaction of time with treatment (difference between drug and placebo in the shape of the time-response curves). When the

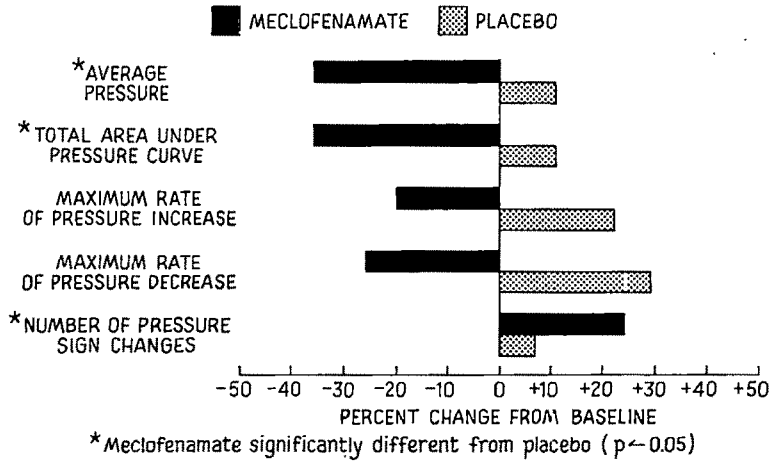

Fig. 1. Overall percent change from baseline—general descriptive measures.

interaction of time with treatment was significant at the 5% level, individual t tests were performed to compare drug response at each study time. These t tests were performed at an overall significance level of 5%.

Blood meclofenamate levels over time were analyzed by a repeated measures analysis of variance. Mean levels at each study time were compared by use of Duncan's multiple range test. The area under the curve was calculated by the trapezoidal method.

For the responses to meclofenamate treatment, Pearson product-moment correlation coefficients were calculated between meclofenamate blood levels and each of the pain parameters, between meclofenamate blood levels and the percentage of change in each of the manometry parameters, and between each of the pain parameters and the percentage change in each of the manometry parameters. Responses at the five time points at which meclofenamate blood levels were obtained were used. Corresponding correlations for responses on placebo (except blood level) were also computed. Correlation coefficients were calculated for each subject and the median coefficient was obtained. Each pairwise median correlation coefficient was tested to see if there was a correlation significantly different than zero.

All testing for statistical significance was performed at $p < 0.05$.

Results

A total of 18 patients entered the study. The overall mean age of the patients was 25.5 years (range 15 to 41). The average age of menarche was 12.0 years (range 9 to 13) and the average age at onset of dysmenorrhea was 15.1 years (range 9 to 39). Menstrual cycles were regular (mean = 28.9 days, range 21 to 35) and of average duration (mean = 5.4 days, range 4 to 8). Thirteen (72.2%) patients had never been pregnant, two (11.1%) had one pregnancy, and three (16.7%) had more than one pregnancy. Sixteen (88.9%) patients had taken one or more medications for dysmenorrhea within 3 months before the study. Entrance history and physical examinations on all patients were either normal or showed minor unrelated findings that would not interfere with the study.

All patients presented for study within 28 hours after the onset of menstruation (maximum = 27 hours; average time to meclofenamate therapy = 8.6 hours; average time to placebo therapy = 9.8 hours). No patients received any nonsteroidal anti-inflammatory drug within 102 hours of undergoing study.

Of the 18 patients entered, two patients were lost to follow-up after one cycle (placebo) and were not included in the crossover analyses of pain or uterine pressure parameters. One patient had a technically unsatisfactory pressure recording on one cycle (placebo) and was therefore excluded from the crossover analysis of uterine pressure parameters. All patients (excluding the one instance of unsatisfactory manometry measurements) were included in the calculation of means and correlation analyses. One patient experienced vomiting after taking study medication (placebo), and two patients received Compazine during the first hour of meclofenamate treatment for symptoms of nausea. These data were included in all analyses.

No patients experienced any drug-related adverse effects during this study.

Subjective response. Average pain intensity was moderate at baseline for both meclofenamate and placebo treatment groups. The differences between meclofenamate and placebo treatments were statistically significant for both total pain relief (TOTPAR) and sum of the pain intensity difference (SPID). The mean total of the pain relief scores was approximately 50% greater with meclofenamate (17.5) than with placebo (11.1), and the mean sum of the pain intensity difference scores was more than twice as great with meclofenamate

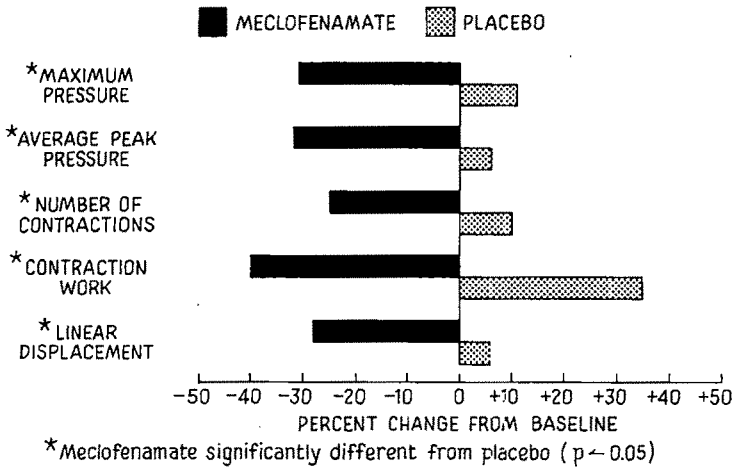

Fig. 2. Overall percent change from baseline—measures of uterine work.

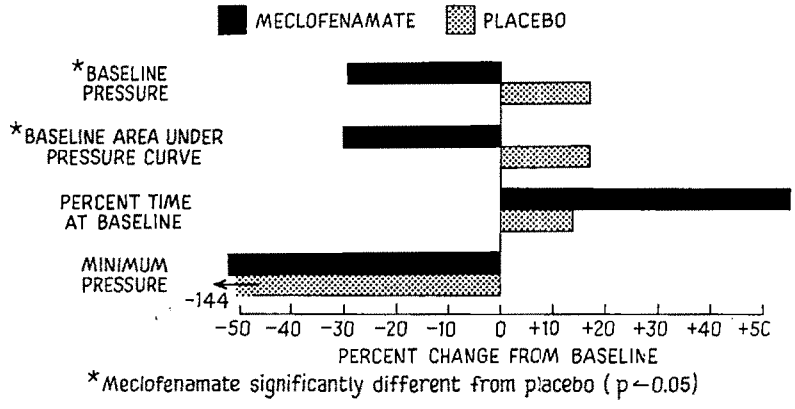

Fig. 3. Overall percent change from baseline—measures of uterine rest.

(7.6) than with placebo (3.4). The differences between meclofenamate and placebo treatments for both pain relief and pain intensity difference were evident as early as 45 minutes after treatment and reached statistical significance at and beyond 1 hour 45 minutes.

Objective response. The mean baseline values for each of the manometry parameters did not significantly differ by treatment group. The mean overall percentage of change from baseline was statistically significantly different by treatment group for 10 of the 14 manometry measures (Figs. 1 to 3). After meclofenamate treatment, a reduction from baseline of 20% to 56% was seen with all parameters except number of pressure sign changes and percent time at baseline, whereas after placebo treatment, an increase of 6% to 35% was seen with all parameters except minimum pressure.

The increase in number of pressure sign changes of 24% with meclofenamate versus 7% with placebo (Fig. 1) reflects an increase during meclofenamate treatment of small frequent pressure changes common in the resting uterus, as opposed to the prolonged rises and falls in pressure seen with untreated uterine contraction waves. Measures of uterine work showed reductions ranging from 25% to 40% after meclofenamate and increases of 6% to 35% after placebo. Five (31%) patients receiving meclofenamate had a complete loss of contractile activity on meclofenamate (number of peaks = 0). A reduction in number of peaks (contractions) to <20% of baseline was experienced by 10 (63%) patients receiving meclofenamate and only three (18%) patients receiving placebo. During placebo therapy, four (25%) patients experienced a twofold or greater increase in the number of uterine contractions as measured by number of pressure peaks.

Twelve of the 14 uterine pressure parameters showed statistically significant differences between meclofenamate and placebo in the shape of the time-response curves. These differences were apparent as early as 30 minutes after medication, were generally

evident at 45 minutes, and became statistically significant at 45 minutes to 1 hour 45 minutes after medication.

Plasma meclofenamate levels. No detectable plasma meclofenamate levels were present for any patient at baseline or after placebo administration. After administration of meclofenamate, mean plasma drug levels increased steadily during the study period, from 0.25 to 4.97 μg/ml. The greatest increase occurred between 15 and 30 minutes after treatment ($p < 0.05$).

Correlations between parameters. After meclofenamate administration, statistically significant correlations were found between blood meclofenamate level and pain relief, pain intensity difference, and percent change in all manometry parameters except contraction work and percent time at baseline. Statistically significant correlations were also found between pain relief and percent change in all manometry parameters except contraction work and between pain intensity difference and percent change in all manometry parameters except contraction work and percent time at baseline. The magnitude of the r values of statistically significant correlations ranged from 0.26 to 0.87.

After placebo administration, statistically significant correlations were found only for pain intensity difference and percent change in linear displacement ($r = -0.51$), and pain intensity difference and number of pressure sign changes ($r = 0.52$). Pain relief showed no statistically significant correlations with any of the manometry parameters during placebo.

Comment

Past studies have suggested that the pain of dysmenorrhea is directly related to the amount of uterine work (high pressures and number of contractions) and inversely related to the quality of uterine rest.[8, 10-14] In this study, simultaneous recording of pain and uterine activity after placebo and drug therapy was shown, for the first time, that a reduction in intrauterine pressure and uterine activity during drug treatment results in a reduction in pain associated with primary dysmenorrhea. Several findings clearly demonstrated the effectiveness of meclofenamate in treating primary dysmenorrhea: (1) statistically significant decreases in both intrauterine pressure and pain; (2) statistically significant correlations between pressure and pain measures during drug therapy; and (3) statistically significant correlations of pressure and pain measures with meclofenamate blood level.

Pain improvement was observed shortly after administration of both drug and placebo. However, this improvement reached a modest, sustained level of response soon after placebo, whereas progressive improvement was observed after meclofenamate. In fact, it appears that maximal effects were not yet reached by the end of 3 hours 15 minutes despite clinically and statistically significant changes much earlier. Comparisons of the meclofenamate and placebo response versus time curves for all pressure measures except minimum pressure do not reveal a similar "placebo effect" for objective responses.

The greatest changes in manometry measurements after meclofenamate therapy occurred in parameters of uterine work (Fig. 2). All parameters of uterine work showed statistical significance of meclofenamate over placebo, with significant differences occuring as early as 45 minutes after ingestion of the drug. Almost two thirds (63%) of the patients receiving meclofenamate experienced a reduction in the number of uterine contraction waves (pressure peaks) to below 20% of their pretreatment levels. By comparison, four (25%) patients receiving placebo experienced at least a twofold increase in the number of uterine contractions. Furthermore, the contractions occurring during meclofenamate therapy showed a 32% reduction from baseline in average peak pressure. The reductions in the frequency and severity of contractions after meclofenamate are reflected in an overall 40% reduction in contraction work, whereas after placebo, contraction work increased by 35%. Linear displacement as a measure of uterine work similarly showed a reduction of 28% with meclofenamate and an increase of 6% with placebo. The rapid reductions in uterine work after meclofenamate therapy and the statistically significant correlations of these reductions with blood meclofenamate level and pain improvement confirm the relationship of uterine work in the development of pain in dysmenorrhea, as suggested in a recently published review.[15]

The moderate increase in percent time at baseline observed for placebo (14%) occurred during a simultaneous increase in baseline pressure of 17%, while the greater increase observed for meclofenamate (56%) occurred simultaneously with a 29% reduction in baseline pressure. Thus patients receiving meclofenamate spent more time at a reduced resting pressure than did those receiving placebo.

Past discussions of the proposed relationship between the uterine activity recorded by objective means and subjective discomfort have been based on little more than clinical conjecture. The consistent correlations found in these data for meclofenamate treatment provide strong evidence that drug therapy directly affects the uterine activity that causes the discomfort of dysmenorrhea. Thus a claim of pain prevention, rather than pain relief, seems highly justifiable.

In the clinical setting, treatment effect may be even greater than that seen in this study. Patients in this study

had discomfort of at least moderate severity before study and then underwent at least 30 additional minutes of baseline uterine pressure recording. In clinical practice, it is recommended that medication be taken at the first indication of discomfort rather than after increased severity of symptoms. Thus meclofenamate may provide even greater therapeutic effect in dysmenorrheic patients treated when symptoms first appear.

Discussion

DR. MICHAEL PHELAN, Jacksonville, Florida (Official Guest). The use of nonsteroidal anti-inflammatory agents for the treatment of dysmenorrhea is commonplace. For many years these drugs were used with no clear understanding of their mechanism of action. Previous studies have indicated that elevated myometrial tonus between contractions is an important factor in both primary and secondary dysmenorrhea. In fact, the basal tone of the uterus may be more of a factor than the rhythm or intensity of contractions in that the elevated uterine tone causes hypoxia of the uterine muscle and therefore pain.[1] Anti-inflammatory agents work by inhibition of prostaglandin synthesis and lowering of the resting tone of the uterus during menstruation.

Previous studies have demonstrated accurate methods of obtaining information and evaluating activity of the uterus during the menstrual period.[2] Drs. Smith and Powell used this technology to evaluate the drug meclofenamate and to show both the efficacy of the drug and the action of the drug on uterine activity. Their study is a double-blind, placebo-controlled, crossover study of 18 patients that compares both the subjective discomfort of dysmenorrhea and the effect of medication on uterine activity. We are shown simultaneous evaluation of pain intensity and pain relief, continuous recording of intrauterine pressures along with monitoring of blood meclofenamate levels. The significant correlations made are those of blood meclofenamate levels with pain relief parameters, blood levels, and reduction of uterine activity as well as diminished uterine activity and pain improvement. The conclusions drawn are that there is statistically significant relief achieved with meclofenamate and that the action can be directly correlated with blood drug levels and the degree of alteration in objective measurements of uterine activity.

Similar studies[3] with the use of intrauterine pressure monitoring and other medications have been done in the past, but none have combined the subjective and objective measurements that the authors used. Most of the comments that can be made on this study are general comments that have been made in regard to all these types of studies. The first and most obvious is the concern that the information gathered on a study group this size cannot be extrapolated to a much larger group, the general population. The fact is that investigators do not claim that their drug will relieve all patients of dysmenorrhea. All that needs to be shown is that the medication is significantly effective in the majority of patients using it when compared with a placebo group. In this study there was "a moderate increase in percent time at baseline uterine pressure during a simultaneous increase in baseline pressure of 17% for placebo." With meclofenamate there was a greater increase in percent time at baseline (56% versus 14%) with a 29% reduction in baseline pressure. Patients receiving meclofenamate spent more time at a reduced resting pressure and therefore experienced less pain.

Smith and Powell stated that there were no adverse effects of the drug, but two patients experienced nausea and were given Compazine. One patient receiving placebo vomited. One of the major drawbacks of using earlier anti-inflammatory agents such as indomethacin

or phenylbutazone was their gastrointestinal side effects. This has been thought to be due to the fact that there is a protective effect by prostaglandins on gastric mucosa.[4] Suppression of prostaglandins therefore allows for gastric upset. Concerns also have been raised regarding long-term use of anti-inflammatory agents. Critics often fail to note, however, that with dysmenorrhea the use of the medication is short term and thus the gastrointestinal effect may not be as significant. Only further experience with the drug will yield that information.

The use of nonsteroidal anti-inflammatory agents for treating secondary dysmenorrhea is also an issue. The fear that arises is that pain relief given by these medications may mask a progressive, damaging process such as endometriosis. These drugs do not give relief to all patients and a trial of drug therapy may actually help select out the patients that need to undergo laparoscopic examination. This article dealt with primary dysmenorrhea, but with endometriosis being found in younger patients this may become a growing concern.

There have been shown to be many effective nonsteroidal anti-inflammatory agents for treating dysmenorrhea, but the studies have been small and "head-to-head" comparisons of drugs are lacking. While there is probably no "best drug" for treating this problem it would be nice to know which medications would carry the highest expectations. Meclofenamate certainly has been shown to give significant relief to patients. It meets the criteria described by Henzl et al.[5] for the "ideal drug" for treatment of dysmenorrhea. It acts by direct interference with the pathogenic process, its use may be limited to the time when an individual suffers the pain, it is highly effective without undue side effects, and the onset of analgesia is prompt. Subjective responses to differences in pain relief and pain intensity were evident as early as 45 minutes after treatment with meclofenamate. The pain relief correlated well with blood drug levels.

In closing I would have to agree with the conclusion of Smith and Powell that "a claim of pain prevention, rather than pain relief, seems highly justifiable."

Dr. William F. O'Brien, Tampa, Florida. My question is regarding the correlation with blood drug levels. It appeared to me that the measurements were taken at a time when blood levels were on the rise and therefore there was automatically an autocorrelation with time. In order to truly look at correlation one would then have to look at the down slope of that to see if the symptomatology and the objective findings correlated there rather than just with time after drug use. I would like a comment on that.

Dr. John Staegie, Durham, North Carolina. I am fascinated by the objective worsening of measures on the placebo. I am wondering if that is an artifact of the prolonged placement of the catheter device itself. If not, could he speculate on the mechanism for the subjective worsening in the presence of objective improvement.

Dr. Smith (Closing). Dr. Staegie, I think the reason that we see worsening over time in placebo-treated patients relates to the natural history of these diseases. We were lucky enough to be able to catch these patients fairly early into their symptoms and the natural course of these patients generally is a worsening over the first 24 to 48 hours. The average time from onset to presentation and start of the monitoring process for the placebo patients was around 8 hours. It was slightly longer for the meclofenamate patients but there was no statistically significant difference. Our feeling is that this is not catheter induced. When we have had an opportunity for long-term monitoring with the catheter we have seen no long-term changes. For example, in earlier techniques with the use of microballoons, many investigators felt that there had to be a 30-minute cooling off period from the time of insertion of the balloon until the time the readings were stable because there was an induction of uterine activity at that point. In our hands we have not seen any changes with placement of the catheter or with long-term use. Paralleling that is the first question about long-term monitoring and whether we see these drugs wear off again. While this study was limited to 3½ hours, the maximal blood effect did not appear to have been reached. In other patients in other studies you can indeed watch these drugs wear off. With monitoring a progressive return to baseline activity can be seen around 6 to 7 hours. Even though we did not make any effort to look at the wear-off period we feel confident that the rise and the parallel change in uterine activity still reflect the effect of our therapy. Whether we can undo that therapy is a separate question.

The question raised in the formal discussion about the response in secondary dysmenorrhea of course is a concern. Obviously any medication used for pain should not cover up the underlying cause. It has been our experience as well as that of other investigators that patients with secondary dysmenorrhea generally do not respond well to the nonsteroidal drugs. As Dr. Phelan alluded, this may almost be a therapeutic challenge. If a patient who is receiving a nonsteroidal drug of any sort does not get at least some improvement, I think you have to be suspicious that you have the wrong diagnosis. The patient has secondary dysmenorrhea. The question of nausea with these drugs and with dys-

menorrhea is a problem. In a larger subjective study of Ponstel, a cousin of meclofenamate, there was a one-half instance of nausea with drug as opposed to placebo. Many of your patients will tell you that a common part of their dysmenorrhea is nausea. This is thought to be due to the gut stimulation by prostaglandin $F_{2\alpha}$, a very potent smooth muscle stimulant; it makes sense that it should cause nausea, vomiting, and diarrhea through gut hypermotility. While we did see two patients in this study who had nausea sufficient to require an antiemetic and they were receiving meclofenamate, our feeling in this study was that it was not related to the drug; however, we do know that roughly 4% to 6% of patients receiving nonsteroidal drugs will have nausea. Dr. Phelan pointed out the significance of baseline activity in our hands, and in the actual correlation numbers, we felt that uterine activity was even more important in the cause of pain. The amplitude and the rate of change and the frequency of uterine contractions appear to be even more important than just baseline activity but more work still needs to be done.

Hysterosalpingographic evaluation of tubal patency after ectopic pregnancy

Dorothy E. Mitchell, M.D., Helen F. McSwain, M.D., James A. McCarthy, M.D., and Herbert B. Peterson, M.D.

Atlanta, Georgia

In the period 1983 to 1985, hysterosalpingography was performed in 76 women after laparotomy to manage ectopic gestations. Clinical characteristics of these women, including their operative findings, were then correlated with the follow-up hysterosalpingography. Study participants were classified into five groups according to surgical management of the ectopic gestation. In each of the five groups, a substantial percentage of those women with a nonpatent fallopian tube (contralateral to the tube bearing the ectopic gestation) on hysterosalpingography had a normal-appearing fallopian tube at laparotomy. Approximately 50% of women with a history of previous pelvic inflammatory disease were found to have nonpatent contralateral fallopian tubes on follow-up hysterosalpingography. (Am J Obstet Gynecol 1987;157:618-22.)

Key words: Hysterosalpingogram, ectopic pregnancy, reproductive outcome after ectopic pregnancy

The dramatic increase in the incidence of ectopic pregnancy has created an increasingly important personal and public health problem. With so many women involved, a clear understanding of reproductive potential after ectopic pregnancy is necessary, yet relatively little information exists to assess such reproductive potential.

To better characterize factors associated with reproductive outcome after ectopic pregnancy, we undertook a prospective study of women undergoing operation for ectopic gestations at Grady Memorial Hospital during the period 1983 to 1985. We attempted to determine the relationship between clinical characteristics identifiable before operation, anatomic characteristics assessed intraoperatively, and postoperative tubal status as measured by hysterosalpingography.

From the Department of Gynecology and Obstetrics, Emory University School of Medicine, and the Centers For Disease Control, Center for Health Promotion and Education, Division of Reproductive Health, Epidemiologic Studies Branch.

Presented by invitation at the Forty-ninth Annual Meeting of The South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 25-28, 1987.

Material and methods

On July 1, 1983, a protocol was established on the Gynecology and Obstetrics Service at Grady Memorial Hospital, whereby all women who underwent tubal operation for an ectopic pregnancy between July 1, 1983, and March 31, 1985, were evaluated in the third postoperative week. At that time hysterosalpingography was scheduled for the proliferative phase of the menstrual cycle (days 7 to 11), with an effort being made to schedule the hysterosalpingography as closely as possible to the sixth postoperative week. Women had a Westgren sedimentation rate determined the day prior to the scheduled hysterosalpingography. If the sedimentation rate was elevated, the hysterosalpingogra-

phy was rescheduled to follow a 10-day course of antibiotics. Women who did not keep follow-up appointments were contacted and encouraged to do so.

All women with ectopic pregnancy during the study period were considered for conservative surgical management. Salpingectomy was performed only if less conservative management was not clinically feasible. Partial salpingectomy was performed in all women with isthmic pregnancies. For ampullary pregnancies, ruptured or unruptured, an attempt was made to perform a linear salpingostomy when such management was considered clinically feasible. Partial salpingectomy was carried out if damage to the tube was extensive or bleeding was otherwise uncontrollable. Although surgical procedures were performed by various surgeons, all used microsurgical techniques without magnification. Adjuvant therapy included instillation of intraperitoneal dextran 70 (Hyskon), 200 ml, and intravenous chlorpromazine and dexamethasone after operation. A detailed description of the woman's pelvis was recorded intraoperatively on a form placed in her medical record for that purpose.

Our study population comprises those women who had a verified ectopic gestation at laparotomy and who completed postoperative follow-up with hysterosalpingography during the study period of July 1, 1983, to March 31, 1985. We attempted to obtain operative reports, descriptions of the pelvic anatomy, and reports on hysterosalpingography for all patients. History of previous pelvic inflammatory disease (PID), intrauterine contraceptive device (IUD) use, previous ectopic pregnancies, and subsequent intrauterine or ectopic pregnancies was obtained through chart review and telephone interviews.

Results

During the study period, 264 women underwent operation for ectopic pregnancies at Grady Memorial Hospital. During the same 21-month period, 11,792 deliveries took place. Thus at this hospital ectopic pregnancies occurred during our study in a ratio of 1:45 deliveries.

Seventy-six (29%) of these 264 women underwent postoperative hysterosalpingography. The ages of these 76 women ranged from 16 to 37 years. While gravidity ranged from 1 to 8, with 17 (22%) being primigravid, parity ranged from 0 to 7, with 29 (36%) of these being nulliparous (Table I).

In 67 women, we obtained history concerning previous PID and IUD use. Of these 67, 20 (30%) had a history of IUD use and 27 (40%) had a history of previous PID. Two women had previous ectopic pregnancies (Table I).

The study participants were classified into five groups according to the surgical management of the ectopic gestation (Table II). Group 1 was composed of the 26 women who underwent total salpingectomy. Postoperative hysterosalpingography showed that 16 of these women had contralateral tubal patency. In six of the 10 women with a nonpatent contralateral tube, these tubes appeared normal at laparotomy.

Group 2 consisted of 26 women who underwent a partial salpingectomy. In 21 of these 26, hysterosalpingography showed a patent contralateral tube. In two of the five women with a nonpatent contralateral tube, these tubes were described as normal at laparotomy.

Group 3 included 13 women managed by linear salpingostomy. On follow-up hysterosalpingography, four had bilateral tubal patency, six had unilateral patency only (four contralateral tubes, two tubes that were operated on), and three had bilateral occlusion. Of the nine women with at least one nonpatent tube, only four

Contralateral obstruction	9	0	8	6
Total	31	9	16	11

were described as having a normal contralateral tube at laparotomy. Two were described as having an abnormal contralateral tube with no description available for three women.

Group 4 consisted of five women who underwent tubal manipulation to induce mechanically abortion of distal tubal pregnancies. Two of these women had nearly complete spontaneous abortions. On follow-up hysterosalpingography, two of these women appeared to have bilateral patency, two had unilateral patency (one tube that was operated on, one contralateral tube), and one had bilateral obstruction. Of the two women with contralateral tubal obstruction on hysterosalpingography, one had a normal contralateral tube at laparotomy.

Group 5 consisted of six women who could not be categorized in any of the above groups. One had evacuation of an abdominal gestation. Two had previous tubal ligations and underwent salpingectomy. One had had two previous ectopic pregnancies and underwent salpingostomy. Another had bilateral tubal gestations managed by right partial salpingectomy and left salpingostomy. Of these six women, all had bilateral obstruction on hysterosalpingography.

We also evaluated, by follow-up hysterosalpingography, the effect of previous PID and IUD use on tubal patency after ectopic pregnancy in the 67 women for whom this information was available (Table III). There were 31 women with no history of previous IUD use or PID. Twenty-one (79.7%) of these had contralateral tubal patency on hysterosalpingography. There were nine women who had used an IUD but had not had PID. All of these had patent contralateral tubes. There were 16 women who had a history of PID but had not used an IUD. Eight (50.0%) had contralateral tubal patency. Eleven women had a history of both IUD use and PID and only five (45.5%) of these had contralateral tubal patency on hysterosalpingography. Six of the 11 women had ipsilateral as well as contralateral tubal obstruction. None of these women had bilateral patency on hysterosalpingography.

Comment

Conditions delaying or preventing the transport of the embryo cause most extrauterine pregnancies. Chronic salpingitis can impair ciliary activity and tubal motility.[1] Although some data suggest that past IUD use does not increase the risk of ectopic pregnancy,[2] two recent case-control studies[3, 4] demonstrate an increased risk of tubal infertility after IUD use, particularly when such use is associated with tubal infection. In our study, 30% of the study population had used an IUD in the past. Forty percent gave a history of previous PID. While we have no control group for comparison, we believe that this prevalence of IUD use and PID in our study population is higher than would be expected for all women receiving care at our institution.

We correlated a history of IUD use and PID with findings at postlaparotomy hysterosalpingography. All women with IUD use but no previous PID showed contralateral tubal patency on hysterosalpingography, while approximately 50% of those with only a history of PID and those with IUD use plus a history of PID showed contralateral patency. Thus a history of previous PID may be an important predictor not only of risk for ectopic pregnancy but also for subsequent tubal patency. IUD use alone did not appear to increase the risk of tubal obstruction in our population.

Patients having follow-up hysterosalpingography were self-selected and thus potentially introduced a selection bias. We have minimal information to compare characteristics of participants and nonparticipants in this regard. However, the minimal relevant demographic and clinical information available suggests no large difference in the two populations. Specifically, of the 188 women not participating in the study, we were able to identify the ages of 95 patients. Ages of these women ranged from 16 to 35 years, similar to the range for the study population. Few data were available to assess a history of PID or IUD use in those not participating in the study. Of the small numbers of records available for review, four of 14 (28%) and three of 15 (20%) indicated a history of PID and IUD use, respectively. These percentages are generally comparable to those of the study population.

Our protocol for managing ectopic pregnancy attempted to maximize subsequent fertility by use of conservative operation, with careful operative technique. One must ask if conservation of the tube bearing the ectopic gestation is in the patient's best interest. In

our patient population, many women with normal-appearing contralateral tubes at laparotomy had nonpatent contralateral tubes by hysterosalpingography. The fact that clinical assessment and inspection alone at the time of laparotomy for an ectopic pregnancy do not accurately correlate with findings at postoperative hysterosalpingography underscores the importance of conservation of fallopian tubes whenever possible. When conservative operation is performed, hysterosalpingography performed after operation may help to better assess the contralateral tubes and the tubes that were operated on. This information may be useful in counseling regarding future fertility and the need for additional surgical intervention.

Discussion

Dr. Edward E. Gahres, Alexandria, Virginia (Official Guest). During the past decade, the incidence of ectopic pregnancy has doubled in most areas of this country. The study of Mitchell et al. has confirmed this fact. It has been reported that as many as 70% of the women who have had an ectopic pregnancy are infertile. The recurrence rate for ectopic pregnancy is at least 10%. Ectopic pregnancy is the fourth leading cause of death in the state of Virginia. The two leading causes of ectopic pregnancy appear to be salpingitis and previous IUD use. It is unfortunate that the presence or absence of salpingitis was not histologically reported in the surgical specimens studied in this study. Histologic evidence of previous salpingitis has been reported by others to vary from 25% to 50% in uterine tubes removed at the time of operation for ectopic pregnancy.

Since many women desire pregnancy after an ectopic pregnancy, some means of evaluating the status of the fallopian tube in these women is desirable so that they can be advised of their chances for successful pregnancy. Laparoscopy with tubal insufflation produced by a dye appears to be the most accurate means for predicting future success,[1] but it is costly and not entirely without dangers to the woman. Hysterosalpingography is easier, safer, and less expensive and may be as accurate as laparoscopy.

Of the five groups of women reported on in this study, the first four groups consisting of 70 women are the ones who might benefit from screening by hysterosalpingography. Of these 70 women, 51 were determined to have unilateral or bilateral tubal patency. It might be of benefit to follow up these women to ascertain how many have attempted pregnancy. The pregnancy rate might determine the usefulness of hysterosalpingography as a predictor of successful future pregnancy.

The finding that all the women with a history of IUD use but no previous history of PID had contralateral tubal patency is unusual. Knowing the type of IUD used might partially explain this fact, since Dalkon Shield users have an ectopic pregnancy rate that is sixfold higher than that of copper-bearing device users. It has been suggested that removing the IUD as a contraceptive will relegate organisms that produce actinomycosis to a nonpathogenic role and decrease the incidence of unilateral salpingitis.

The presence of *Chlamydia trachomatis* antibody has been reported to be indicative of past tubal disease. The testing for this antibody might be useful as an additional screen for predicting future successful pregnancy.

As Dr. Mitchell has indicated, this study may be useful in counseling women in regard to future fertility.

Dr. Lynn Borchart, Greenville, South Carolina. Dr. Mitchell, have you observed the possible beneficial effect of the hysterosalpingogram itself in the subsequent pregnancy in comparing patients who have been treated for ectopic pregnancy in similar fashions?

Dr. Herbert G. Hopwood, Jr., Arlington, Virginia. I would like to ask Dr. Mitchell one question. Does she contemplate joining in the future the new avant-garde wave of starting the person with suspected ectopic pregnancy on a regimen of methotrexate? Has she planned to do any type of study of those patients?

Dr. Jaroslav F. Hulka, Chapel Hill, North Carolina. I enjoyed the fact that the IUD did not get a "bum rap" in causing ectopic pregnancy in this study, but my concern has to do with those patients that were not studied. A total of 79 patients underwent hysterosalpingography in a total of more than 240 patients. Could you comment at all about the characteristics of those that were not studied? Were the 79 representative of your population?

Dr. H. Oliver Williamson, Charleston, South Carolina. I would like to ask if the authors looked specifically for salpingitis isthmic a nodosa. We hear of salpingitis and IUD usage, but the occurrence of this entity, I would think, should be picked up in a series this large on histologic examination as well as on a hystero-

salpingogram. I did not see that. I would ask specifically did they note it?

Dr. Mitchell (Closing). Yes, there are going to be continuing studies. At this time we just wanted to follow up those individuals who had ectopic pregnancies in this particular group of 76 women. We have persistently followed them up because they are somewhat transient, and that also answers Dr. Hulka's question. We have had 30 intrauterine pregnancies in the 76 individuals, so we are continuing follow-up on these individuals and have had only three repeat ectopic pregnancies. We are very pleased with these results. I think that the most difficult problem we have is because our patient population at Grady Hospital is so transient. Most individuals do not have telephone numbers when we try to call 6 weeks later. They have moved or are just not available and that is very difficult for us, but these are individuals whom we have counseled as much as we can. It may be a point of a resident being able to convince them to come back to Grady Hospital or to come to Grady Hospital as their base more than some of the other 200 that we were unable to follow up. We would like to improve that and we would like to report on all the patients, but that is not possible in our patient population as I think you can imagine. As far as the kind of IUD, we do not have that information. Most of the time it is very nice for us just to know that they had an IUD, again considering the population. Right now we are in the process of doing some chlamydial testing at Grady Hospital, and I think that will become one of the main aspects we are hoping to correlate with future studies on ectopic gestations in our institution. As to methotrexate, yes, I would very much like to think about using that if we can start getting our patients in earlier. Our patient population also is associated with difficulty in coming in so early. Patient education has helped, but many of these individuals come in after rupture and obviously we would not be able to give them methotrexate. I do think that is the next thing we would like to do or at least think about. No, we do not look specifically for salpingitis isthmic a nodosa, but I think that if we continue to do these studies we will come up with a subgroup of those individuals. As far as the treatment that you just asked about, I think we will just have to look at the numbers that have had intrauterine pregnancies and divide up those groups. A lot of these women did get pregnant rather quickly afterward so that might go along with your question.

Transurethral ultrasound-guided oocyte retrieval for in vitro fertilization

Santiago L. Padilla, M.D., William J. Butler, M.D., Jeffrey P. Boldt, Ph.D., Richard H. Reindollar, M.D., Sandra P. T. Tho, M.D., Gerald B. Holzman, M.D., and Paul G. McDonough, M.D.

Augusta, Georgia

Thirty-nine follicular aspirations for in vitro fertilization were performed in 30 patients. Oocyte retrieval was performed by laparoscopy in 21 cases and ultrasound-guided transurethral aspiration in 18 cases. All procedures were performed by the same ovarian stimulation protocol and the same aspirating needle. In the laparoscopy group 150 oocytes were recovered from 177 follicles aspirated (85%). The fertilization rate was 69% (104/150) and cleavage rate, excluding triploidy, was 82% (85/104) for oocytes obtained by laparoscopy. Five clinical pregnancies occurred in the laparoscopy group for a pregnancy rate of 24% per cycle and 25% per transfer. In the transurethral ultrasound-guided group 77 oocytes were recovered from 103 follicles aspirated (75%). The fertilization rate was 79% (61/77) and cleavage rate, excluding triploidy, was 90% (55/61). Three pregnancies occurred for a pregnancy rate of 17% per cycle and 18% per transfer. None of these differences were statistically significant. Transurethral ultrasound-guided oocyte retrieval is a feasible alternative to laparoscopy for in vitro fertilization. (Am J Obstet Gynecol 1987;157:622-6.)

Key words: Ultrasound, fertilization, oocyte

From the Department of Obstetrics and Gynecology, Medical College of Georgia.

Presented by invitation at the Forty-ninth Annual Meeting of The South Atlantic Association of Obstetricians and Gynecologists, Hot Springs, Virginia, January 25-28, 1987.

Reprint requests: Santiago L. Padilla, M.D., Department of Obstetrics and Gynecology, GBMC Physician's Pavilion, Suite 207, 6701 N. Charles St., Baltimore, MD 21204.

Laparoscopy is the usual method of oocyte retrieval for in vitro fertilization. Pregnancy rates per cycle range from 10% to 30% in most successful programs, indicating that the procedure may need to be repeated several times in many women. The least expensive and the least invasive procedure for oocyte retrieval should

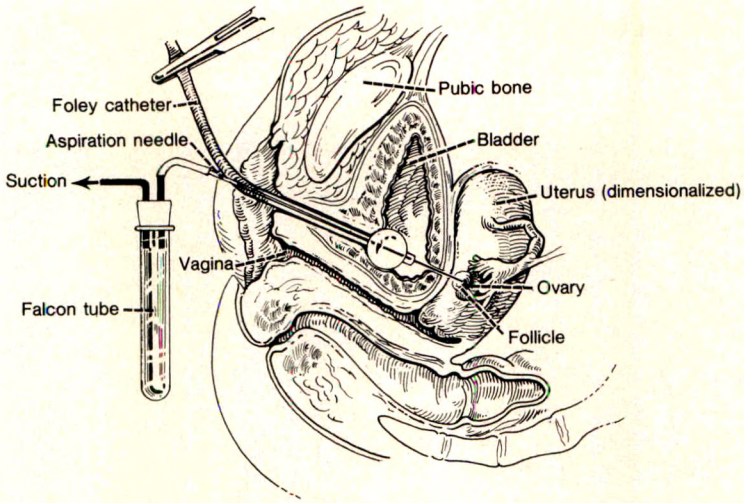

Fig. 1. Diagram of the transurethral follicular aspiration system.

be used as long as the pregnancy rate will not be affected.

In 1981 Lenz et al.[1] were the first to report successful oocyte recovery by using ultrasound-guided follicular aspiration. Since then several techniques using transabdominal,[1-4] transvaginal,[5, 6] and transurethral[7] methods with or without transducer-attached needle guides have been described with variable success. Ultrasound guidance allows oocyte retrieval in patients with inaccessible ovaries that would not otherwise be candidates for laparoscopic retrieval.

In this article we report on our experience at the Medical College of Georgia with ultrasound-guided transurethral follicular aspiration for in vitro fertilization and compare these results with those of laparoscopic retrievals done by the same team of physicians with identical follicular recruitment protocols and embryo laboratory techniques.

Material and methods

Thirty-nine follicular aspirations for in vitro fertilization were performed in 30 patients at the Medical College of Georgia from July 1985 through July 1986. All cycles performed during this time were included in the study. Group 1 consisted of 21 cycles in 16 patients in whom oocyte retrievals were performed by three-puncture laparoscopy. Group 2 consisted of 18 oocyte retrievals performed in 16 patients in whom ultrasound-guided transurethral follicular aspiration was used. Two patients who underwent laparoscopic aspiration on the first cycle and then selected ultrasound-guided aspiration on a subsequent cycle are included in the data. The protocol for the ultrasound-guided aspiration was approved by the Human Assurance Committee of the Medical College of Georgia. All patients were given the option of ultrasound aspiration regardless of their ovarian accessibility, and informed consent was obtained. The indications for in vitro fertilization in group 1 were tubal factor (n = 13), idiopathic infertility (n = 4), male factor (n = 3), and cervical factor (n = 1). The indications in group 2 were tubal factor (n = 17) and cervical factor (n = 1).

Follicular recruitment consisted of 100 mg clomiphene citrate (Serophene; Serono Laboratories Inc., Randolph, Massachusetts) and 150 IU human menopausal gonadotropin (Pergonal; Serono) for 5 consecutive days, starting on cycle day 3 or 5. Follicular monitoring by daily ultrasonographic and estradiol measurements was started on the sixth day of treatment and subsequent human menopausal gonadotropin injections were individualized based on these parameters. When a dominant follicle ≥18 mm and two secondary follicles ≥14 mm were observed, together with a rising estradiol response, 5000 IU human chorionic gonadotropin (hCG) was given and oocyte retrieval scheduled 35 hours later. Serial blood samples drawn 1 or 2 days before the day of hCG administration and at 9 AM, 12 noon, 4 PM, and 10 PM on the day of hCG administration were assayed for both luteinizing hormone and progesterone to detect a spontaneous luteinizing hormone surge.

Oocyte retrievals were performed as outpatient procedures under general or regional anesthesia. The laparoscopic aspirations were done with 100% CO_2 pneumoperitoneum, a second puncture for an atraumatic grasping forceps (R. Wolf Medical Instruments Corp., Rosemont, Illinois) and a third puncture for the aspirating needle.

The transurethral ultrasound-guided aspirations were performed by inserting the aspirating needle through a side slit made on a 20 French Foley catheter after cutting 0.5 cm from the tip of the catheter

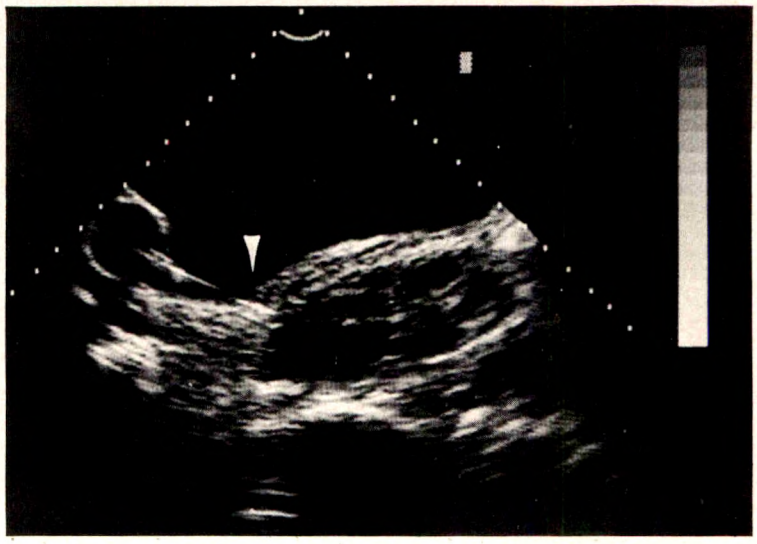

Fig. 2. Longitudinal real-time sector scan. The aspirating needle tip can be seen in the bladder wall *(arrow)* before entering a preovulatory follicle.

(Fig. 1). The catheter was used to empty, rinse, and fill the bladder with warm Ringer's lactate. Simultaneous ultrasound guidance was performed transabdominally with an ATL 4000 sector scanner and a 3.0 MHz transducer. Once the follicle to be punctured was identified the tip of the aspirating needle was guided to the bladder wall adjacent to the follicle. The position of the tip of the needle was verified by transverse and longitudinal scanning, and then the needle was advanced into the follicle (Fig. 2). The needle used in both groups was a 22 cm 14-gauge single-lumen Teflon-lined needle with an internal diameter of 1 mm (Rocket USA, Branford, Connecticut) attached to a 10 ml sterile tissue culture tube (Falcon No. 3033). Aspiration was done by continuous wall suction at 100 to 110 mm Hg with a thumb control. If the oocyte was not found in the original aspirate, the follicle was flushed with an equal volume of sterile culture media containing 100 IU/ml sodium heparin.

The oocytes collected were classified as mature or immature based on morphologic appearance of the cumulus and corona cells. Mature oocytes were incubated for 6 to 7 hours and immature oocytes for 24 to 30 hours in Ham's F10 with 7.5% heat-inactivated serum before insemination with 50,000 to 500,000 washed motile sperm. Oocytes were examined for evidence of fertilization 14 to 18 hours after insemination by removing cumulus and corona cells with a glass micropipette. Fertilized oocytes were transferred to Ham's F10 containing 15% serum. Unfertilized oocytes were transferred to fresh insemination medium and reinseminated with 50,000 to 500,000 washed motile sperm obtained from a second fresh semen sample from the husband. Cleaving embryos were transferred 55 to 80 hours after oocyte retrieval. Triploid embryos were not transferred. The luteal phase was supported with 12.5 mg progesterone in oil administered intramuscularly for 4 days followed by 10 days of 25 mg progesterone vaginal suppositories administered twice daily.

A serum β-subunit human chorionic gonadotropin (β-hCG) titer was drawn 13 to 15 days after transfer, and if positive it was repeated weekly until a gestational sac and fetal pole could be identified. Real-time ultrasonography was scheduled 4 to 5 weeks after transfer. A clinical pregnancy was diagnosed as two elevated serum β-hCG titers with histologic or ultrasonographic evidence of pregnancy. Statistical evaluation was performed by χ^2 analysis.

Results

Oocyte recovery rates for laparoscopic retrievals (group 1) and ultrasound-guided oocyte retrievals (group 2) are shown in Table I. The oocyte recovery rate was not significantly different between the groups. In group 1 a mean of eight follicles were aspirated per procedure, which is higher than a mean of six follicles per procedure for group 2. Consequently, in group 1 a higher mean number of oocytes was collected per procedure than in group 2 (seven versus four, respectively). None of these differences were statistically significant.

Table II illustrates the fertilization, cleavage, and pregnancy rates for the study groups. Fertilization and cleavage rates were slightly better for the ultrasound group but the difference did not reach statistical sig-

Table I. Comparison of oocyte recovery rate between laparoscopic and ultrasound-guided oocyte retrieval for in vitro fertilization

	Group 1 (laparoscopy)	*Group 2 (ultrasound)*
No. of retrievals	21	18
No. of follicles aspirated	177	103
No. of oocytes collected	150	77
Recovery rate (%)*	85	75

*No significant differences.

Table II. Fertilization, cleavage, and pregnancy rates of laparoscopic and ultrasound-guided oocyte retrieval for in vitro fertilization

	Laparoscopy	*Ultrasound*
No. of retrievals	21	18
No. of ooctyes collected	150	77
No. of fertilized oocytes*	104 (69%)	61 (79%)
No. of triploid*	12	2
No. of embryos transferred*	85 (82%)	55 (90%)
No. of clinical pregnancies	5	3
Rate per transfer (%)*	25	18
Rate per retrieval (%)*	24	17

*No significant differences.

nificance. The clinical pregnancy rate of the laparoscopy group (25% per transfer and 24% per retrieval) was not statistically different from the clinical pregnancy rate of the ultrasound group (18% per transfer and 17% per retrieval).

All laparoscopies and ultrasound-guided oocyte retrievals were well tolerated by the patients. Surgical complications in the laparoscopy group included a wound hematoma that resolved with conservative management and one urinary tract infection. One patient in the ultrasound group developed a urinary tract infection.

Postoperative hematuria in the ultrasound group was estimated to be <50 ml per patient and cleared within 6 hours of the procedure in all patients.

Comment

The results presented above indicate that oocyte aspiration by the transurethral ultrasound-guided method compares favorably with laparoscopic retrieval. We found no significant differences between the two methods with regard to oocyte retrieval, fertilization, cleavage, or pregnancy rates. These initial results are encouraging, although further experience with the transurethral-guided method will be required to draw definitive conclusions as to whether pregnancy rates are enhanced or compromised by this method.

When in vitro fertilization was first used in a clinical setting, ultrasound technology had not developed to its current level of capability and resolution; thus laparoscopy was the only viable option available for oocyte retrieval. Before the availability of ultrasound-guided methods, several surgical procedures were often required before the in vitro fertilization cycle so that the ovaries were made accessible for follicular aspiration.[8, 9] The advent of modern ultrasound technology has enabled in vitro fertilization centers worldwide to use ultrasound-guided aspiration as the method of choice for oocyte retrieval[1-7] and has eliminated the need in most cases for surgical intervention to maintain ovarian access. In fact, ultrasound-guided aspiration is actually made easier in cases in which the ovary is fixed by adhesions because the ovary is not able to move away from the aspirating needle. We now routinely perform transurethral-guided ultrasound aspiration in approximately 80% of our patients who undergo in vitro fertilization and have yet to encounter a patient in who we fail to retrieve at least one oocyte. The use of ultrasonography avoids exposure of the oocyte to the high concentration of CO_2 that occurs during laparoscopy when pneumoperitoneum is established with 100% CO_2. Exposure to CO_2 has been associated with poor in vitro embryo development in rabbits.[10]

The transurethral approach has several advantages, as well as disadvantages, over other ultrasound-guided techniques. Transabdominal puncture, used by several groups,[1-4] has the disadvantage that the aspirating needle passes through the abdominal wall, as well as the anterior and posterior bladder walls. In addition, several punctures through the abdominal wall are generally required. Another approach favored in several in vitro fertilization centers is the transvaginal method, wherein the aspirating needle is passed through the vaginal wall and into the ovary.[5-6] Although this technique has been used with success, it may require the use of specially modified vaginal ultrasound transducers and needle guides that are quite expensive. This method also requires puncture through an unsterile vaginal mucosa that can be well vascularized under the influence of ovarian steroids, both conditions that might increase the morbidity associated with the procedure. In our experience the transurethral method is associated with very low morbidity. In addition, if the ovaries are located high in the pelvis the bladder may still have to be entered from the vagina to reach the follicles when a transvaginal approach is used.[6] An advantage of the transvaginal method is that it is more practical than the transurethral route when the ovaries are located either behind the uterus or in the cul-de-sac. Further studies to compare the transurethral, transvaginal, and transabdominal aspiration tech-

niques will be necessary to determine which one is the best for in vitro fertilization.

Dr. Jeffrey Kerotkin, Atlanta, Georgia. Did you have any trouble stabilizing the ovary under ultrasound guidance? Was there any difficulty with the ovary moving out of the way when you tried to puncture it to retrieve the eggs?

Dr. Padilla. Yes, we did. We used two maneuvers to stabilize the ovary. One of them was to attach a tenaculum to the cervix, pull the cervix the way you pull a utero-ovarian ligament, and stabilize it. The other maneuver was transabdominal pressure. You push the ovary down and pull it from down below and you can stabilize it and reach it.

Dr. Robert Bowden, Lynchburg, Virginia. This method was described by Stuart Campbell, and there are multiple advantages of not requiring an operating room facility, which is certainly cost-effective, and not having the problems of general anesthetic, etc. He also stated that as they got into the technique their retrieval rate became equal to the retrieval rate with laparoscopy and that also they did find that the amount of fluid that was put into the bladder was critical as far as postoperative hematuria and the possibility of a paravesical hematoma. Would you comment on that aspect.

Dr. Padilla. I think that you have to look at the amount of fluid. We pretty much used the amount of fluid that was necessary to visualize the ovaries. We have seen the other data and they showed, like we show, that there is no difference in terms of recovery rate. In terms of the volume of fluid used, it varies from patient to patient. Sometimes you can see with 300 ml and sometimes you require 400 or 450 ml to visualize. We have not seen any difference in terms of the incidence of hematuria, and our incidence has been minimal using a 14-gauge needle.

Unknown speaker. Dr. Padilla, you have mentioned that one of the purposes of this was to make the technology less invasive and less expensive if you use general or spinal anesthetic. Is it really cheaper or less invasive?

Dr. Padilla. The only thing that was cheaper was the professional charge. We did offer a local anesthetic to the patients but they all wanted at least an epidural; one patient desired a saddle block and she tolerated it pretty well. She felt the ovarian punctures but she did not feel the bladder manipulation. We did discount the professional fee but it takes about as much time to do the ultrasound aspiration as to do the laparoscopy; probably ultrasonography takes a little longer than laparoscopy.

TRANSACTIONS OF THE SEVENTH ANNUAL MEETING OF THE SOCIETY OF PERINATAL OBSTETRICIANS

The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores

Anthony M. Vintzileos, M.D., Sue Ellen Gaffney, R.N.C., M.S.N., Lauren M. Salinger, R.N.C., M.S.N., Vasilios G. Kontopoulos, M.D., Winston A. Campbell, M.D., and David J. Nochimson, M.D.

Farmington, Connecticut

The relationships among the fetal biophysical profile, umbilical cord blood pH, and Apgar scores were investigated in 124 patients undergoing cesarean section before the onset of labor. Based on a standard for the diagnosis of fetal acidosis of an umbilical cord arterial pH <7.20, the sensitivity, specificity, and positive and negative predictive values of the fetal biophysical profile score were 90%, 96%, 82%, and 98%, respectively. When the combination of a nonreactive nonstress test and absent fetal breathing was used as the "abnormal test," the sensitivity, specificity, and positive and negative predictive values were 100%, 92%, 71%, and 100%, respectively. The efficacy of the fetal biophysical profile to indicate fetal acidosis was found to be superior to the 1- and 5-minute Apgar scores in sensitivity and positive predictive value. These data suggest that the biophysical profile is very accurate in the identification of the fetus with acidemia. The first manifestations of fetal acidosis are nonreactive nonstress testing and loss of fetal breathing; in advanced acidemia fetal movements and fetal tone are compromised. A new protocol of antepartum fetal evaluation is suggested based on individual biophysical components rather than the score alone. (Am J Obstet Gynecol 1987;157:627-31.)

Key words: Fetal biophysical profile, umbilical cord pH, Apgar score, fetal acidosis, cesarean section

The fetal biophysical profile (nonstress test, fetal breathing movements, fetal movements, fetal tone, amniotic fluid volume, and placental grading) has been shown to be more accurate in the identification of the compromised fetus than any other single test during the antepartum period.[1-7] The most important factor in the sensitivity of this testing method is the combination of acute (nonstress test, fetal breathing movements, fetal movements, fetal tone) and chronic (amniotic fluid volume) markers of the fetal condition. All previous studies have attempted to correlate the fetal biophysical profile with parameters of perinatal outcome after either spontaneous or induced labor.[1-8] The inherent drawbacks of these studies have included the long interval between the performance of the biophysical assessment and the birth of the infant, with the corresponding effects of labor and drugs on the fetus. To minimize these problems, we examined the relationship between the fetal biophysical profile and perinatal outcome, as determined by umbilical cord blood pH and Apgar scores, in patients undergoing cesarean section before the onset of labor.

Material and methods

This prospective study included 124 consecutive patients with singleton pregnancies and gestational ages between 26 and 43 weeks who were delivered by cesarean section. The patients had intact membranes and were not in labor. Infants with congenital anomalies were excluded. In all cases a fetal biophysical profile

Table I. Efficacy of the fetal biophysical variables to predict fetal acidosis

†1 versus 3, $p < 0.005$; 2 versus 3, $p < 0.001$.

was determined within 6 hours before the cesarean section. Most of the patients (95 of 124; 77%) were transferred to the University of Connecticut Health Center because of pregnancy complications. The primary indications for delivery/cesarean section were: severe pregnancy-induced hypertension (55 patients; 45%), elective repeat cesarean section (29 patients; 23%), intrauterine growth retardation with breech presentation (15 patients; 12%), placenta previa (14 patients; 11%), fetal macrosomia (four patients; 3%), and other (seven patients; 6%). Of the 124 cesarean sections, 70 (56%) were performed under epidural anesthesia and the remaining 54 (44%) were performed under general anesthesia.

The fetal biophysical profile was determined according to a method previously described. Each biophysical variable was scored as 2, 1, or 0 according to the criteria cited in a previous study.[5] The maximal score was twelve and the minimal score was 0. Immediately after delivery of the infant, a segment of the umbilical cord was doubly clamped and blood was separately collected from both artery and vein into plastic heparinized syringes. Blood samples were then transported in ice for acid-base analysis, which was done by a means of an automatic pH/blood gas analyzer (Corning Medical Model 178). All pH measurements were performed within 5 minutes after the blood collection. Apgar scores were measured at 1 and 5 minutes by a neonatal fellow or attending physician who used a stopwatch. For the purpose of this study, fetal acidosis was defined as umbilical cord arterial pH <7.20.

Statistical analysis was by χ^2 or Fisher's exact test when appropriate (for categoric variables) and Student's *t* test (for continuous variables).

Results

A total of 124 patients were included in the study. Mean gestational age was 34 weeks (range 26 to 43 weeks). The fetal biophysical profile score was ≥8 in 102 patients (82%) and ≤7 in the remaining 22 patients (18%). A total of 20 fetuses with acidemia were encountered (cord arterial pH <7.20). The efficacy of the biophysical scoring as well as of the individual biophysical components to predict fetal acidosis is shown in Table I. In the 102 fetuses with biophysical scores of ≥8 the mean (±SD) cord arterial pH was 7.28 (±0.04) (range 7.10 to 7.38). In this group two fetuses (2%) were acidotic, both of which had scores of 8 with nonreactive nonstress test and absent fetal breathing. Thirteen fetuses with scores between 5 and 7 had a mean (±SD) cord arterial pH of 7.19 (±0.06) (range 7.19 to 7.40), and nine fetuses (69%) were acidotic. Nine fetuses with scores of 4 had a mean (±SD) cord arterial pH of 6.99 (±0.10) (range 6.85 to 7.19), and all (100%)

Positive predictive value		*Negative predictive value*	
%	*n*	%	*n*
82	18/22	98	100/102
71	20/28	100	96/96
44	20/45	100	79/79
35	20/57	100	67/67
71	10/14	91	100/110
100	9/9	90	104/115
50	7/14	88	97/110
38	9/24	89	89/100
14	1/7	84	98/117

were acidotic. The differences in the cord arterial pH values of these three groups were statistically significant (7.28 versus 7.19, $p < 0.005$; versus 6.99, $p < 0.001$).

The relationship between the fetal biophysical activities (acute markers of the fetal condition) and cord arterial pH was also investigated. For the purpose of this analysis four groups were identified. Group 1 included 96 fetuses with reactive nonstress test and/or fetal breathing present (lasting more than 30 seconds). This group was further subdivided in 50 fetuses who had both reactive nonstress test and breathing present (mean cord arterial pH 7.28; range 7.20 to 7.38), 29 fetuses with reactive nonstress test and fetal breathing absent (mean cord arterial pH 7.28; range 7.20 to 7.38), and 17 fetuses with nonreactive nonstress test and fetal breathing present (mean cord arterial pH 7.28; range 7.20 to 7.38). Group 2 (17 fetuses) had nonreactive nonstress test and fetal breathing absent with normal movements and tone; the mean cord pH of this group was 7.20 (range 7.10 to 7.40). Group 3 (four fetuses) had nonreactive nonstress test and absent fetal breathing with compromised (present, but not normal according to the criteria[5]) movements and/or tone; mean cord arterial pH of this group was 7.16 (range 7.11 to 7.20). Group 4 (seven fetuses) had all biophysical activities absent and the mean cord arterial pH was 6.95 (range 6.85 to 7.02). These cord arterial pH differences between the four groups were statistically significant ($p < 0.005$). The frequency of fetal acidosis in groups 1, 2, 3, and 4 was 0%, 59% (10 of 17), 75% (three of four), and 100% (seven of seven), respectively. The efficacy to predict fetal acidosis (cord arterial pH <7.20) according to the combination of reactive nonstress test and/or fetal breathing present as the normal test, and nonreactive nonstress test and fetal breathing absent as the abnormal test, was found to be 100%, 92%, 71%, and 100%, respectively (Table I).

Of the individual biophysical components (Table I), the nonstress test and fetal breathing had the highest sensitivities and negative predictive values (both 100%); their combination (with nonreactive nonstress test and fetal breathing absent as the abnormal test) increased the specificity and positive predictive value to 92% and 71%, respectively. Fetal tone had the highest positive predictive value (100%) but low sensitivity (45%).

When the fetal biophysical profiles of the 20 fetuses with acidemia were analyzed, the following were observed. All 20 fetuses had nonreactive nonstress test and absent fetal breathing. When movements and tone were normal (10 fetuses), the mean (±SD) cord arterial pH was 7.16 (±0.03); among these 10 fetuses there was only one death, which was attributed to prematurity. Nine survived with no sequelae. When the movements and tone were partially compromised (three fetuses), the mean (±SD) cord arterial pH was 7.15 (±0.04) and none died. When movements and tone were absent (seven fetuses), the mean (±SD) cord arterial pH was 6.95 (±0.06); four of these seven fetuses died, two survived with major hypoxic sequelae, and one survived with no sequelae. The mean cord arterial pH was significantly lower when all fetal biophysical activities were absent (6.95 versus 7.15 or 7.16, $p < 0.001$). Of the 20 fetuses with acidemia, seven (35%) had amniotic fluid pockets <1 cm and nine (45%) had pockets <2 cm in vertical diameter. Of the 104 nonacidotic fetuses, seven (7%) had amniotic fluid pockets <1 cm and 15 (14%) had pockets <2 cm in vertical diameter. These differences were statistically significant (35% versus 7%, $p < 0.005$; and 45% versus 14%, $p < 0.01$).

There were 39 fetuses with a 1-minute Apgar score <7 and only 13 were acidotic; of the 85 fetuses with a 1-minute Apgar score ≥7, seven were acidotic. There were 15 fetuses with a 5-minute Apgar score <7 and only eight were acidotic; of the 109 fetuses with a 5-minute Apgar score ≥7, 12 were acidotic. Table II compares the efficacy of the fetal biophysical profile score (≤7), nonreactive nonstress test and fetal breathing absent, and Apgar scores (≤7) at 1 and 5 minutes in predicting the fetus with acidemia. The sensitivity of the combination of nonreactive nonstress test and breathing absent was significantly better than the 1- and 5-minute Apgar scores ($p < 0.005$ and $p < 0.001$, respectively), and the sensitivity of the biophysical score was better than the 5-minute Apgar score ($p < 0.005$). In terms of positive predictive value, the combination of nonreactive nonstress test and breathing absent was significantly better than the 1-minute Apgar score ($p < 0.005$) and the biophysical score was better than the 1-minute Apgar score ($p < 0.001$). There were no differences in specificity and negative predictive value.

Comment

The present data suggest that there is a significant relationship between the fetal biophysical profile and fetal acid-base status at the time of testing. The sensi-

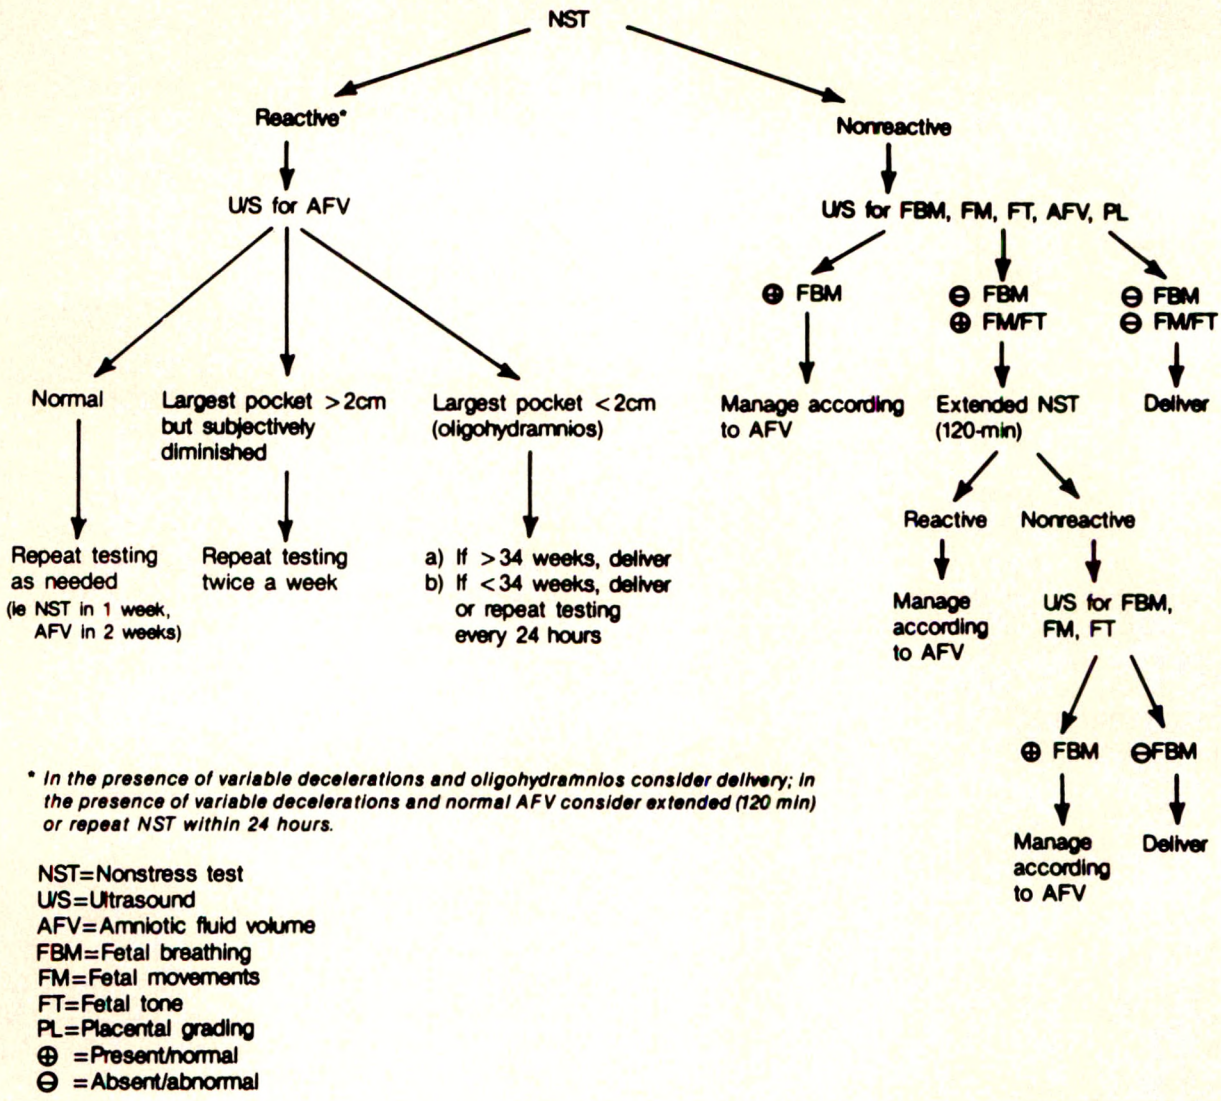

Fig. 1. Protocol of antepartum fetal evaluation with intact membranes.

tivity of this testing method was 100% if the individual fetal biophysical components were considered rather than the score.

The first manifestations of fetal acidosis are nonreactive nonstress testing and loss of fetal breathing; in advanced acidemia fetal movements and tone are compromised. The acute markers of the fetal condition were also found to correlate with the long-term outcome of the 20 fetuses with acidemia. When all biophysical activities were absent (seven fetuses) the outcomes included four deaths, two survivors with major neurological sequelae, and one normal survivor. The above concept of different levels of sensitivity to hypoxia and acidosis of the fetal central nervous system centers, which control the biophysical activities,[9] is very important in the correct interpretation and application of the information obtained from the biophysical monitoring of the fetus. Indeed, the sensitivity in predicting the acidotic fetus was 100% when the combination of nonreactive nonstress test and breathing absent was used as the abnormal test.

Amniotic fluid volume, unlike the other biophysical variables, is not acutely influenced by alterations in fetal central nervous system function and is a chronic marker of the fetal condition. It is included in the fetal biophysical profile because of the high correlation between decreased amniotic fluid volume and increased incidence of abnormal pregnancy outcome.[1-5, 10] The present data support an increased frequency of oligohydramnios in the presence of fetal acidosis. Fetuses with decreased amniotic fluid volume are at a high risk for cord compression and in utero death regardless of the presence or absence of the other biophysical variables. The presence of a Grade III placenta was not found

to predict fetal acidosis; nonetheless, in our institution placental grading is still included in the fetal biophysical profile because Grade III placentas have been found to be associated with increased incidence of abnormal fetal heart rate patterns (44.4%) and abruptio placentae (14.8%) during labor.[5] The value of including placental grading is to alert the physician during the intrapartum period to the presence of a Grade III placenta.

Considering the physiology and pathophysiology of fetal biophysical activities, and because the sensitivity for predicting the fetus with acidemia is best determined by the combination of nonreactive nonstress test and fetal breathing absent as the abnormal test, we recommend an alternative scheme of antepartum fetal evaluation based on the individual biophysical components rather than the score (Fig. 1). This scheme includes assessment of both an acute (nonstress test and/or fetal breathing) and a chronic (amniotic fluid volume) marker. We have applied this protocol of antepartum fetal evaluation to 6543 fetuses over a 4-year period, and we have never encountered a fetal death of a structurally normal fetus within a week after a reassuring biophysical assessment.[11]

This alternative protocol of antepartum fetal evaluation, without including the scoring of the biophysical variables, will increase the sensitivity of this testing method and eliminate the problems encountered in the clinical interpretation and application of the obtained information. Our present data also suggest that the fetal biophysical profile is a better predictor of the acidotic fetus than the Apgar scores. This should not be surprising because the fetal biophysical profile was designed to predict fetal asphyxia, while Apgar scores were designed to assess the need and extent of neonatal resuscitation. The understanding of the physiology and pathophysiology of the fetal biophysical activities, as well as the significance of oligohydramnios, is imperative for the proper clinical application of this tool and therefore for the improvement of the quality of perinatal care.

Fetal cerebellar growth unaffected by intrauterine growth retardation: A new parameter for prenatal diagnosis

E. Albert Reece, M.D., Israel Goldstein, M.D., Gianluigi Pilu, M.D., and John C. Hobbins, M.D.

New Haven, Connecticut, and Bologna, Italy

Nineteen pregnant women with a clinical suspicion of intrauterine growth retardation and with gestational age confirmed by early ultrasound examination were referred to our departments for sonographic evaluations. Multiple biometric parameters were obtained, including the transverse cerebellar diameter by use of the electronic calipers of the machine. A prenatal diagnosis of intrauterine growth retardation was made in all cases based on: (1) the transverse cerebellar diameter being consistently correlated with gestational age as predicted by the last menstrual period, whereas most of the other measurements were consistently discrepant with the transverse cerebellar diameter by more than 2.5 weeks (i.e., more than 2 SD above the mean), and (2) the estimated fetal weight of all fetuses being equal to or less than the tenth percentile for gestational age. Neonatal examination confirmed all fetuses to be growth retarded with birth weights at or below the tenth percentile for gestational age. These findings indicate that growth of the transverse cerebellar diameter is unaffected by intrauterine growth retardation; thus this sonographic measurement may serve as an independent and reliable correlate of gestational age against which potential deviations of growth may be compared. (Am J Obstet Gynecol 1987;157:632-8.)

Key words: Cerebellum, intrauterine growth retardation, ultrasound, gestational age

Intrauterine growth retardation (IUGR) occurs in about 2% to 10% of all infants born in developed countries.[1] Despite overall advances made in perinatal medicine, the exact cause of IUGR remains unclear, and the mortality rate among these fetuses is still higher than in normal pregnancies.[2] In light of the increased death rate associated with IUGR, early detection of reduced fetal growth is essential so that intense fetal surveillance may be instituted, permitting the detection of fetal compromise and the opportunity for intervention before the fetus is in jeopardy. Current methods used to detect fetal growth retardation are hampered by the lack of precise estimate of gestational age in most cases, leading to difficulty in determining whether a fetus is truly growth retarded, constitutionally small, or appropriately grown but with an incorrect gestational age. It would be desirable, however, for some biometric parameters to be unaffected by growth aberrations, thus providing a standard against which disparate growth

could be compared and the diagnosis of fetal growth retardation established.

The purpose of this communication is to report a study in which fetuses suspected of having growth retardation were examined sonographically to determine whether a comparison between the gestational age predicted by the transverse cerebellar diameter and that predicted by multiple other biometric parameters could be used as an adjunctive method in the prenatal diagnosis of IUGR.

Patients and methods

A prospective study was conducted in 19 pregnant women with known last menstrual periods confirmed by first-trimester or early second-trimester ultrasound examination, who were referred to the perinatal unit at Yale–New Haven Hospital or the pathophysiology unit of the University of Bologna with a clinical suspicion of fetal growth retardation. These fetuses were subjected to sonographic examinations, and the measurements were obtained by use of the electronic calipers of the ultrasound machines (General Electric RT 2600 and RT 3000; GE Corp., Rancho Cordova, California). In each patient several biometric measurements were obtained, including the biparietal diameter, the occipitofrontal diameter, the calculated head circumference, cephalic index, abdominal circumference, estimated fetal weight, long bone measurements, and the transverse cerebellar diameter. The latter measurement was obtained from the outer-to-outer margins of the cerebellum, after its identification in the posterior fossa (Fig. 1). Some patients received serial examinations at approximately 2- to 3-week intervals. Cerebellar growth in normal pregnancies has been previously studied, and nomograms have been generated.[3, 4] In our study[4] we found a high degree of correlation ($p < 0.0001$) between transverse cerebellar diameter and gestational age, with the overall 2 SD being ±2.4 weeks. Before 24 weeks the transverse cerebellar diameter in millimeters was equivalent to the gestational age in weeks. However, slight flattening of the growth curve was seen beyond this point. The growth pattern was best described by a third-order polynominal equation. A determination of IUGR was

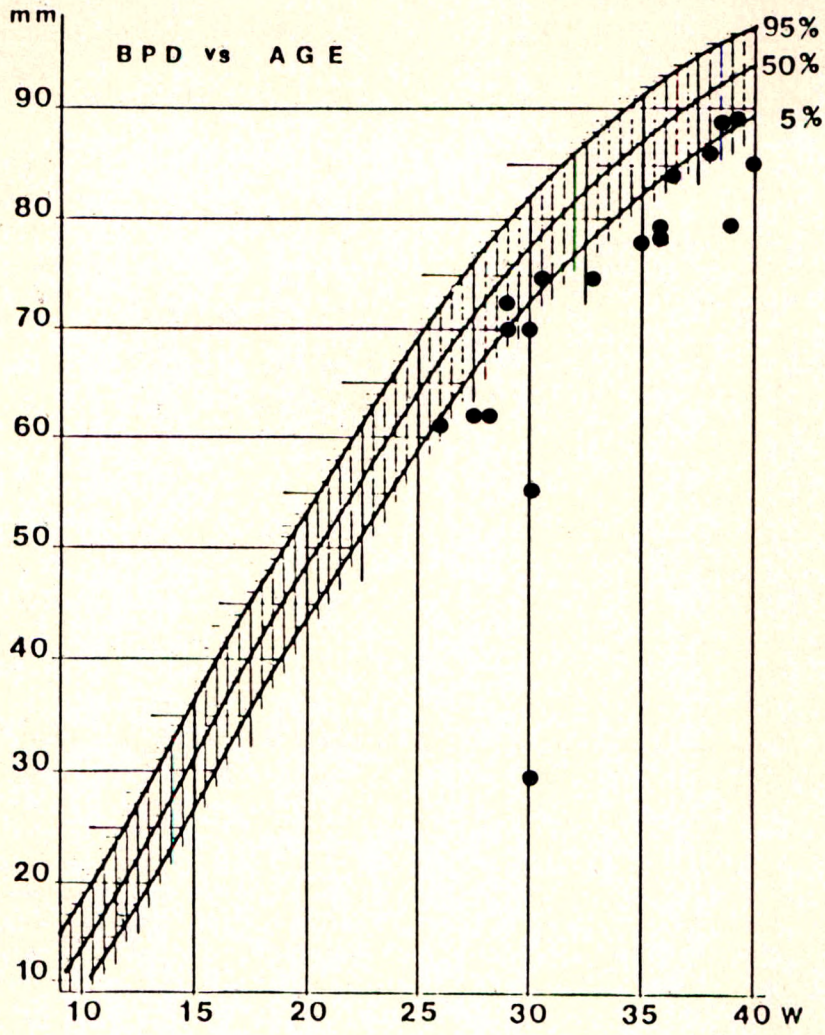

Fig. 3. Biparietal diameters *(BPD)* of normal fetuses by Jeanty and Romero. Scatter points indicate the biparietal diameter of patients in this study fell at or below the fifth percentile. (Reproduced with permission from Jeanty P, Romero R. Obstetrical ultrasound. New York: McGraw-Hill, 1984.)

made by use of this nomogram if the estimated fetal weight was at or below the tenth percentile for the gestational age predicted by the transverse cerebellar diameter, and if a discrepancy between the gestational age by the transverse cerebellar diameter and the other measurements existed and was greater than 2.5 weeks. Neonatal information collected at birth included the birth weight, length, ponderal index, and a determination as to whether the fetus was growth retarded based on the percentile rank, as measured by the scale of Usher and McClean[5] or by the Lubchenco nomogram.[6]

Results

Pregnant women referred to our departments because of a suspicion of IUGR underwent diagnostic ultrasonography. The gestational ages of these pregnancies ranged from 24 to 40 weeks. In all 19 consecutive patients in whom the diagnosis of IUGR was made, the transverse cerebellar diameter correlated with the gestational age as predicted by the last menstrual period, and it remained within the mean for the gestational age (Fig. 2). The remaining biometric parameters predicted a fetus of a much earlier gestational age. The disparity in gestational age (between that predicted by transverse cerebellar diameter and that predicted by the remaining biometric parameters) was consistently greater than 2.5 weeks (i.e., greater than 2 SD above the mean). Additionally, the measurements of the biparietal diameter, the abdominal circumference, and the femur length were at the fifth percentile for gestational age (Figs. 3 to 5). Antenatal estimation of fetal weight by sonography revealed fetuses to be under the tenth percentile (Fig. 6). Neonatal evaluations revealed all fetuses to be growth retarded. Their birth weights were equal to or less than the tenth percentile for gestational age (Fig. 7).

Comment

This study demonstrates that the transverse cerebellar diameter remained unaffected by fetal growth retardation, whereas most biometric parameters measured sonographically were significatly affected by the overall growth retardation process. The consistent disparity between the gestational age predicted by transverse cerebellar diameter and that predicted by most other biometric parameters was remarkable. In this relatively small series there were no false negative or false positive diagnoses.

The cerebellum is well protected in the fetal head, and it has been shown in experimental animals that this organ is the last to be affected by a decrease in blood flow.[7] Additionally, the fetus responds to decreased uteroplacental perfusion by circulatory adjustment, by which the blood supply to the brain is conserved at the expense of blood flow to the skin, muscle, and lungs.[8] Behrman et al.[7] studied the regional distribution of blood flow to term primate fetal brain in both control and asphyxiated animals. They found that the blood flow to the cerebellum was significantly higher than that to the cerebral cortex in the control group. However, in asphyxiated fetuses, although cortical blood flow decreased, blood flow to the cerebellum remained unchanged. Others have reported vasodilation of cerebellar vessels in asphyxiated fetal lambs.[9] In light of these remarkable findings one has to presume the hemodynamic adjustments observed under experimental conditions are operative in the human fetus and are important in the preservation of normal cerebellar growth, even in the presence of severe fetal growth retardation.

The inability to ascertain gestational age by ultrasound parameters in the third trimester has proved to be a major cause of undiagnosed growth-retarded fetuses. Various methods have been proposed for detecting IUGR; however, varying accuracy and detection rates have been reported with sensitivity ranging from 44% to 90%, specificity from 88% to 93%, and predictive values from 40% to 100%.[10] Some of these diagnostic methods include assessment of the biparietal diameter growth, in which there may be evidence of late flattening resulting in the biparietal diameter measuring consistently below normal. Other measurements include a formula combining the fetal abdominal circumference and the biparietal diameter to estimate the fetal weight. The rationale for this method is based on the

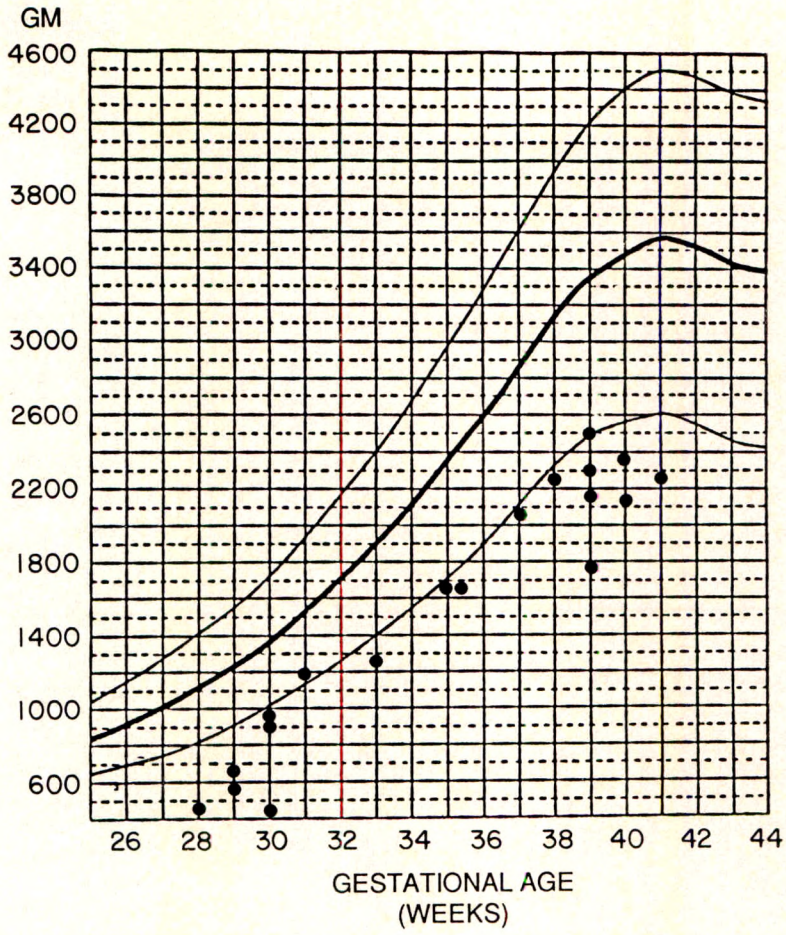

Fig. 7. Neonatal birth weight according to Usher and McClean using a sea-level population plotted against gestational age. Note the birth weights of all our patients at/or below the tenth percentile depicted. (Reproduced with permission from Usher R, McClean F. J Pediatr 1969;74:901.)

concept that the liver is the most severely affected intra-abdominal organ in decreased fetal growth and that it might lend itself to the early detection of IUGR.[11] The ratio of head circumference to abdominal circumference is another method utilized in an attempt to differentiate between the types of growth-retarded fetuses.[12] The fetal ponderal index has also been evaluated as a predictor for IUGR.[13] Other methods introduced to diagnose IUGR but found to be less sensitive include the total intrauterine volume or the 1 cm pocket of fluid.[14, 15] In spite of these various methods attempting to identify the growth-retarded fetus, a major source of frustration lies in the inability to ascertain the precise gestational age. Unfortunately, the very biometric measurements used to demonstrate abnormal growth are also the ones used to determine gestational age. This dilemma could be overcome if a parameter were available that was relatively spared by alterations in fetal growth and therefore could be used as a standard for gestational age against which all other biometric parameters could be compared. This preliminary report strongly suggests that transverse cerebellar diameter represents such a parameter.

In conclusion, measurement of the transverse cerebellar diameter can be performed on most fetuses, independent of the fetal head shape, or even when the fetus is in a direct occiput posterior position. The present lack of precise diagnostic criteria for IUGR leads to an inaccurate antenatal diagnosis. Utility of the transverse cerebellar diameter may serve as an independent and reliable indicator of gestational age and a standard against which aberrations in fetal growth may be compared.

A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor

Jay D. Iams, M.D., Francee F. Johnson, R.N., B.S.N., Richard W. O'Shaughnessy, M.D., and Lou C. West, R.N., B.S.N.

Columbus, Ohio

In a prospective trial we enrolled 157 women at increased risk of preterm birth, randomly assigning women in a ratio of 1:2 to receive either frequent (≥5 days/wk) nursing contact, education in preterm labor symptoms, and self-palpation of uterine activity (group E, n = 50), or daily nursing contact, preterm labor education, and the Term Guard home uterine activity monitor (group EM, n = 107). Comparison of the rate of preterm birth, the incidence of preterm labor and successful tocolysis, and the mean birth weight and gestational age revealed no significant differences and suggested that beneficial effects previously attributed to monitored contraction data may in fact be the result of frequent (five or more times per week) nursing contact and careful attention to preterm labor symptoms and perceived contractions. (Am J Obstet Gynecol 1987;157:638-43.)

Key words: Term Guard uterine activity monitor, preterm birth, preterm labor

Early detection of increased uterine activity may lead to more effective tocolysis in women at risk of preterm labor. Self-palpation of uterine activity as part of an educational program for women at risk of preterm labor has been reported by Herron et al.[1] to increase the percentage of patients with preterm labor who are candidates for tocolysis, thereby reducing the rate of preterm birth. Newman et al.[2] reported, however, that self-detection of uterine contractions correlated poorly with tocodynamometer recording of uterine activity and suggested that self-detection may not be a reliable early method of detection of preterm labor. Ambulatory tocodynamometry, with the Term Guard uterine activity monitor, has been reported by Katz et al.[3-5] in a series of articles to be a safe and reliable method of uterine activity assessment that has shown promise in the early identification of women in preterm labor.

Because women using such a monitor are necessarily in daily contact with a nurse whose advice and support may lead to earlier identification of preterm labor, we

designed a prospective random trial comparing pregnancy complications and outcomes in women at increased risk of premature delivery. One group used the Term Guard uterine activity monitor (Tokos Medical Corporation, Santa Ana, California) and a control group received instruction in self-palpation and a similar level of nursing education and support.

Material and methods

One hundred fifty-seven pregnant women at increased risk of preterm labor were recruited from area physicians (n = 136) and The Ohio State University prenatal clinic (n = 21). In all, there were 42 physicians or practice groups who contributed subjects to the study. None of the subjects had had preterm labor in the current pregnancy before enrollment, and all were between 20 and 34 weeks' gestation at entry. Informed consent was obtained, and subjects were then randomized in a ratio of 1:2 to one of two groups, E or EM, according to a protocol approved by The Ohio State University Human Subjects Review Committee. Group E patients received an initial educational session, usually lasting 60 to 75 minutes, about the symptoms and signs of preterm labor and were taught self-palpation of uterine activity. They were asked to note the presence of symptoms of preterm labor, listed in Table I, and to palpate uterine activity for 1 hour twice daily. Each group E subject was contacted by a nurse at the Columbus Term Guard Monitoring Center daily on weekdays and as needed on weekends. Women in group EM were similarly educated at entry and instructed as well in the use of the Term Guard home uterine activity monitor. They were asked to note symptoms and to record contractions for 1 hour twice daily. Group EM patients were contacted by telephone daily including weekends to transmit and interpret monitor strips and symptoms. Women in both groups were instructed to call the monitoring center if symptoms and/or increased contractions (more than four per hour) were noted and persisted for 1 hour despite lateral bed rest and oral hydration. Women with persistent symptoms and/or contractions in excess of their established baseline contraction frequency were sent to the doctor's office or to the labor and delivery suite for a cervical examination, unless the doctor specifically ordered otherwise, for example, requested instead an additional hour of home monitoring and hydration or, for those patients receiving oral tocolysis, an additional dose of medication.

Participating physicians were asked to follow broad standard guidelines of care for preterm labor, using intravenous ritodrine or magnesium sulfate or subcutaneous terbutaline in standard doses when preterm labor was diagnosed. The definition of preterm labor used in the March of Dimes Multicenter Preterm Birth Prevention Project was suggested, with parenteral tocolysis recommended for persistent uterine contractions numbering eight or more per hour if the cervix was already 2 cm dilated or 50% effaced but requiring cervical change if the cervix was <2 cm dilated and less than 50% effaced. Prophylactic tocolysis was discouraged unless the patient had a history of preterm delivery. For purposes of data analysis, preterm labor was defined as admission to the hospital and administration of either an intravenous tocolytic or multiple doses of a subcutaneous tocolytic. Once parenteral tocolysis was begun, oral tocolytics were continued in all cases until ≥35 weeks' gestation. Participating physicians were visited at least once during the study by a Tokos Medical Corporation representative and/or a project nurse who reinforced the study protocols. Medical and nursing in-service educational programs were provided to the larger referring hospitals in the area. All nurses providing daily contact and monitor interpretation were employed at the Columbus Term Guard Monitoring Center and received a standard orientation and education program provided by the Tokos Medical Corporation. A system of "primary nursing" was adopted shortly after the study started, wherein each patient in both groups had one nurse who served as her principal contact. All nurses had subjects in both groups. A nurse was available to all patients in both groups 24 hours a day, 7 days a week. The monitoring center staff was aware of the crude preterm birth rates for both groups as the study progressed.

Each birth before 37 completed weeks of gestation was reviewed by the principal investigator with the attending physician and the Term Guard nursing staff to confirm gestational age and compliance with protocol guidelines.

Table I. Symptoms of preterm labor

Uterine contractions ≥4/hr, with or without pain
Low backache
Increased vaginal discharge
Menstrual-like cramps
Pelvic pressure
Abdominal cramping
Spotting

Results

One hundred fifty-seven women had been delivered of their infants as of mid-November, 1986 (107 in group EM and 50 in group E). There were nine women (8.4%) in group EM and six women (12%) in group E who dropped out of the study. This difference is not significant. The most common reason for dropout in both groups was that the patient and/or the doctor found daily telephone contact or contraction data to be

*All births ≥37 weeks were averaged as 37 weeks to avoid skew caused by postdate pregnancies.

annoying or confusing. None of these 15 women was delivered within 7 days of discontinuing the protocol, and their inclusion would not affect the results of the study. There were 98 patients in group EM and 44 in group E who continued to use the service until delivery or until 37 weeks' gestation; these 142 women constitute the population used to obtain the results.

Risk factors for preterm delivery and other demographic variables were similar in each group, as displayed in Table II. Some women had more than one risk factor. Previous preterm birth and twins were the most common reasons for enrollment in both groups. There were no subjects with triplet gestations in either group.

The incidence of prematurity, defined at 35 and 37 weeks, and the mean gestational age and birth weight are shown in Table III. Thirty-five weeks was selected for analysis because all participating physicians were aggressive in the use of parenteral tocolytics and were fully compliant with protocol guidelines through 35 completed weeks. Some did allow preterm labor after 35 weeks to progress without treatment in several instances, evenly distributed between groups E and EM. The differences in preterm birth rates are not statistically significant; analysis at 34 and 36 weeks also reveals no significant difference.

Births before 37 completed weeks were extensively reviewed and categorized, as displayed in Table IV, according to the diagnostic category that directly led to the preterm delivery: preterm labor, preterm prematurely ruptured membranes, or a medical or obstetric indication unrelated to preterm labor or preterm premature rupture of the membranes. Those preterm births that followed preterm labor were further categorized as (1) following a failed tocolytic attempt, (2) allowed by a physician because of a gestational age >35 completed weeks, or (3) occurring because of advanced cervical dilation >4 cm on arrival. None of the differences in Table IV is significant. In no case was preterm labor before 35 weeks allowed to progress without treatment unless the cervix was already >4 cm dilated on arrival.

The incidence of preterm labor was 36% in group E and 39% in group EM, as shown in Table V. The number of episodes of preterm labor eligible for treatment, the overall use of prophylactic and therapeutic tocolytics, and the gestational age at onset of preterm labor are also not statistically different.

Weeks gained from study entry until delivery or until 37 weeks averaged 7.35 ± 4.2 for the 40 patients in group E and 9.0 ± 4.4 for the 94 in group EM who did not have an indicated preterm birth. Considering only those women in each group who developed preterm labor, the number of days gained from first appearance of preterm labor until delivery or until 37 weeks' gestation was 18.6 ± 21.0 in group E and 10.9 ± 12.9 in group EM. These differences are not significant.

During the course of the study, several physicians expressed concern that participation would lead to an excessive number of unscheduled office visits for cervical examination because of the frequency and intensity of contact with subjects in both groups. We therefore looked also at the frequency of unscheduled visits, defined as an office or labor and delivery suite visit initiated by the Term Guard nurse. There were 60 unscheduled visits in 44 group E patients (1.36 ± 1.28 per subject) and 146 unscheduled visits in 98 group EM patients (1.49 ± 1.37 per subject). Seventy-three percent of group E and 74% of group EM subjects made at least one unscheduled visit.

Sample size is always an issue in clinical studies. Before beginning this study, we based estimates of sample size on rates of preterm birth seen in our preterm labor clinic population, defining risk according to the Creasy scoring system.[12] The rate of preterm birth (<37 weeks' gestation) was approximately 30%. We postulated a 30% reduction in deliveries before 37 weeks with the use of the Term Guard monitor, which would require 230 subjects in each group to achieve a one-tailed p of 0.05 and a power of 0.8. Using a 2:1 randomization schema, we planned to enroll 170 women in group E and 340 in group EM to achieve a harmonic mean of 230. However, entry criteria for this study proved to be substantially more stringent than those of the Creasy system, yielding a study population with a higher inherent risk of preterm birth. A revised power analysis at this point in the study reveals that a harmonic mean of 90 to 100 subjects (E = 75, EM = 150) will be necessary to detect a drop in the preterm birth rate from 50% to 30%. A sufficient number of undelivered subjects have been enrolled to reach that goal.

Analysis of the data reported here by the method reported by Young et al.[7] reveals that the sample size is sufficient to have detected a 50% fall in the preterm delivery rate and sufficient as well to have detected a 10-day gain from the first episode of preterm labor with a power of 0.8 and a p of 0.05.

Comment

The physiologic basis of contraction monitoring rests on a series of reports from multiple investigators correlating increased uterine contraction frequency during pregnancy and risk of preterm birth.[4, 8-10] Although normal and increased levels of uterine activity at each gestational age remain to be established, it appears from these reports that women destined to be delivered before term do, in fact, have more frequent contractile

activity throughout the latter half of pregnancy when compared with women who are delivered at term.

The next question is how best to use this association to prevent unnecessary preterm births. Main et al.[9] appear to have been successful in using the association as a screening tool to identify a subset of their population at increased risk of preterm delivery, something which had proved to be difficult with more traditional historical and risk scoring approaches in their population of indigent black women.[11]

Herron et al.[1] taught self-assessment of uterine activity to women who had been already identified by a risk score as being at high risk for preterm labor. They demonstrated a substantial drop in the preterm delivery rate, and their methods were soon widely imitated with variable results.[6, 12] The key features of preterm birth prevention programs patterned after the report by Herron et al. are identification of women at increased risk of preterm labor and intensive patient and staff education about the symptoms and signs of preterm labor. In this approach, the patient is a key participant in the early identification of preterm labor. The patient must recognize the signs and/or symptoms of preterm labor and initiate contact with the health care system. The report of Newman et al.[2] that high-risk women identified only 15% of their recorded contractions cast doubt on the reliability of a patient-based "alarm system" for the early identification of preterm labor. The development of technology capable of reliably recording and transmitting uterine activity data in a timely fashion seemed a good way to avoid concerns about patients' perceptions of uterine activity, and the reports by Katz et al.[3-5] were promising. Perhaps overlooked in the development and deployment of this approach is the increased frequency of patient contact with the health care system, in this case the Term Guard nursing staff. The study design reported here allows comparison of clinical outcomes in two groups of high-risk women who all received frequent nursing contact. The groups differed primarily in the manner in which the uterine activity was assessed.

The principal end point for this study is the number of women reaching 35 and 37 weeks at delivery. We believe this is the most appropriate outcome for analysis since it represents the answer to the first question posed by the patient and her doctor when considering use of such a system: Will this approach prevent the birth of a premature infant? Other end points such as eligibility for tocolysis may be potentially misleading: If the contraction detection system does detect contractions and if contractions are the basis for the diagnosis, then of course the system is always 100% "successful." The addition of cervical examination findings is helpful, but they may also be highly subjective and interpreted differently according to the patient's previous obstetric history, when used to determine the initiation of tocolysis. All studies of preterm labor are affected by these uncertainties, so it seems best to place greatest emphasis on the least subjective end points such as gestational age and birth weight.

The similarity of all outcomes in groups E and EM is striking: The incidence of preterm labor, preterm delivery, and successful tocolysis is similar. Women using the monitor were not sent in for examination or treated prophylactically more often than those using self-palpation. Physicians who enrolled their patients in the study often forgot which study group the patient was in, suggesting that they perceived similarly the care received by both groups. The nursing staff seemed to move from a primarily contraction frequency–based approach in the early weeks of the study to a more global, symptoms-plus-contraction frequency–based approach as their experience grew. The similarity in outcome for groups E and EM indicates that advantages previously attributed to the monitored contraction data may in fact be the result of frequent nursing contact and careful attention to symptoms and perceived contractions. This in turn has implications for the prenatal care of women at increased risk of spontaneous preterm delivery: They should be educated about both preterm labor symptoms and contraction frequency as early markers of preterm labor and should be given ample opportunity to relate symptoms to a welcoming and supportive health care provider. We did not simultaneously enroll a third group of women who received a standard level of nursing and physician contact and therefore cannot draw any conclusions about whether frequent contact, with or without a monitor, is superior to current practice in reducing the incidence of preterm birth in high-risk patients. Such a study is now underway. We doubt, however, that a system based principally on contraction detection without equal attention to symptoms will be of use in reducing preterm births.

Another question unanswered by this study is the identification of specific subsets of the population at risk for preterm labor who might benefit most or least from tocodynamometer recording of uterine activity. Newman et al.[13] have reported increased levels of uterine activity among women with twins, which might make them more or less susceptible to any benefit of home tocodynamometry. Similar questions remain unanswered for women with uterine anomalies, incompetent cervices, and vaginal bleeding. Katz et al.[14] have also reported success with home monitoring in the management of oral tocolysis, with contraction frequency used as a guide to dosage adjustment, in 60 patients with preterm labor who used the Term Guard compared with 60 non–randomly selected matched control subjects. The study reported here specifically excluded

women treated for preterm labor before entry, but a similar prospective randomized trial of home monitoring in these patients is also underway.

In summary, this prospective random trial of intensive patient education and nursing support with and without a home uterine contraction monitor indicates that increased attention should be paid to the role of frequent and supportive patient contact in preterm birth prevention; the role of ambulatory contraction monitoring has yet to be defined.

We wish to express thanks to the physicians of central and southeast Ohio who enrolled their patients in this study, and to the Tokos Medical Corporation.

Chronic oral terbutaline tocolytic therapy is associated with maternal glucose intolerance

Elliott K. Main, M.D., Denise M. Main, M.D., and Steven G. Gabbe, M.D.
Philadelphia, Pennsylvania

Plasma glucose determinations were performed 1 hour after a 50 gm oral glucose load in 30 patients receiving long-term terbutaline therapy (20 to 40 mg/day for at least 1 week) and 247 normal control patients. A total of 63% of patients receiving terbutaline had an abnormal 1-hour value (≥140 mg/dl), an incidence much higher than that of control subjects (17.8%) ($p < 0.0001$) for a relative risk of 3.54 (95% confidence intervals of 2.29 to 5.42). Mean 1-hour values were 112.1 mg/dl for control subjects and 149.8 mg/dl in the terbutaline group ($p < 0.0001$). All abnormal values were followed by a 3-hour 100 gm oral glucose tolerance test. A total of 15.9% of the glucose tolerance tests performed in the control group (2.8% overall) were abnormal as opposed to 52.6% (33.1% overall) in patients receiving terbutaline ($p < 0.01$). Nine patients were studied before and after terbutaline therapy. Results obtained during administration of terbutaline were significantly higher (102.2 mg/dl before therapy versus 145.2 mg/dl during therapy). We conclude that treatment with oral terbutaline appears to be associated with impairment of glucose tolerance in pregnancy. (Am J Obstet Gynecol 1987;157:644-7.)

Key words: Terbutaline, tocolysis, glucose intolerance

Treatment with intravenous β-sympathomimetic tocolytic agents can cause significant deterioration of maternal glucose homeostasis.[1, 2] We have previously shown that chronic oral ritodrine therapy does not produce significant clinical effects on glucose tolerance.[3] Over the last 2 years, we have largely switched to oral terbutaline therapy out of consideration for cost and dosing frequency. The effects of long-term (≥1 week) oral terbutaline therapy during pregnancy have not been studied in detail. The metabolic consequences of such treatment could be of critical importance because patients may require extended therapy with terbutaline at the time of greatest gestational insulin resistance, 26 to 30 weeks of gestation. This study was undertaken to determine the effects of long-term oral terbutaline therapy on carbohydrate tolerance in the early third trimester.

Subjects and methods

The study included all patients in our high-risk obstetric practice between January 1985 and July 1986. A 1-hour 50 gm oral glucose screening test was performed routinely at 26 to 30 weeks' gestation (92% of patients were studied between 27 and 29 weeks of gestation). The screening test was usually done in the morning when patients were fasting or after they had eaten a light meal. All plasma glucose levels that were ≥140 mg/dl after the screening test were considered abnormal and a 3-hour 100 gm oral glucose tolerance test was performed. The 3-hour glucose tolerance test was done in the morning after an overnight fast.

The diagnosis of gestational diabetes was made when two or more abnormal values were observed during the 3-hour glucose tolerance test. As recommended by the National Diabetes Data Group,[4] a fasting value of ≥105 mg/dl, a 1-hour value of ≥190 mg/dl, a 2-hour value of ≥165 mg/dl, and a 3-hour value of ≥145 mg/dl were considered abnormal. To further quantitate the degree of abnormality of the 3-hour glucose tolerance test, the area under the curve was roughly calculated by adding together half the fasting value, the 1- and 2-hour values, and half of the 3-hour value.[5] Patients with abnormal 3-hour glucose tolerance tests were given intensive dietary education. Patients with persistent fasting hyperglycemia (≥105 mg/dl) after 7 to 10 days of dietary management were treated with insulin.

Blood was obtained from all subjects by venipuncture and glucose determinations were performed on plasma samples by the glucose oxidase method. Patients were excluded from the study if they were known to have insulin-dependent diabetes or previously diagnosed gestational diabetes, if they were exposed to intravenous corticosteroids or β-sympathomimetics within 72 hours of testing, or if they were receiving β-sympathomimetic agents other than terbutaline.

Patients in the terbutaline group were treated with

	$p < 0.01$*	

*χ^2 analysis.

20 to 40 mg/day in divided doses for at least 1 week before testing. Terbutaline therapy was continued during the glucose tolerance testing without change in dosing interval. There were five patients who had received corticosteroid treatment but none within 72 hours of glucose testing. The rate of abnormality in 1-hour glucose screening in these women (3/5 or 60%) was similar to that of the overall group (63%), so these patients were combined.

Birth weight was that recorded at delivery. Gestational age was based on the best obstetric estimate according to last menstrual period, ultrasonography (more than 90% of patients had at least one scan before 28 weeks' gestation) and serial office examinations. Birth weight index was calculated by dividing the measured birth weight by the fiftieth percentile birth weight. The fiftieth percentile weight was derived from a normal curve developed for patients in Philadelphia.[6]

Results were analyzed by Student's t test for continuous data (two tailed), χ^2 for proportions, and relative risk and confidence intervals as applicable.

Results

In total, 277 patients were studied, including 30 receiving oral terbutaline therapy for the prevention of recurrent preterm labor and 247 control subjects. Women treated with terbutaline and untreated women were comparable with respect to age (30.7 versus 31.9 years), prepregnancy weight, and history of diabetes in first-degree relatives (Table I). Only 6.6% of the treated women and 5.3% of the control women were less than 25 years of age. Gestational age at the time of testing was also similar between treated and untreated patients (28.2 ± 2.3 versus 28.7 ± 1.6 weeks). All comparisons were statistically insignificant at the $p > 0.05$ level by Student's t test or χ^2 analysis.

The proportions of women who had an abnormal 1-hour screening test and an abnormal 3-hour glucose tolerance test on follow-up testing are reported in Table II. In the untreated group, 44/247 or 17.8% had an abnormal screening test while 19/30 or 63% of the terbutaline-treated group had values ≥140 mg/dl ($p < 0.0001$, χ^2 analysis). The relative risk (odds ratio) for an abnormal 1-hour screening test during terbutaline administration compared with that for control women is 3.54 with 95% confidence intervals of 2.29 to 5.42. Thus we would anticipate that at least 40.8% of women receiving long-term oral terbutaline therapy would have an abnormal 1-hour screening test.

Of the 3-hour oral glucose tolerance tests, results were abnormal in 7/44 (15.9%) of the control women compared with 10/19 (52.6%) in the terbutaline group ($p < 0.01$, χ^2 analysis). Overall rates of gestational diabetes were 2.8% in control women but 33% for the terbutaline group. Furthermore, five of the 10 (50%) patients with gestational diabetes who were given terbutaline had persistent fasting and postprandial hyperglycemia and were treated with insulin therapy. Two of seven (29%) patients with gestational diabetes in the control group also required insulin.

Mean 1-hour screening values for the terbutaline and control groups are illustrated in Fig. 1. The control population in the current study had a mean plasma glucose level of 112.1 ± 25.6 mg/dl while the terbutaline group had a significantly higher mean of 149.8 ± 29.9 mg/dl ($p < 0.0001$). We have previously studied the effects of ritodrine with an identical study design,[3] and these results are also shown in Fig. 1. The mean plasma glucose values for the control and ritodrine populations in that study were similar (117.7 and 117.0 mg/dl).

In the current study, the calculated area under the 3-hour glucose tolerance test curve was nearly 100 mg/dl greater in the terbutaline group than in the control women (493.5 ± 124.4 versus 395.7 ± 68.8). This was highly significant at $p < 0.0001$ (Student's t test).

We studied nine patients before and during terbutaline therapy. Terbutaline treatment was administered as described for the larger group (20 to 40 mg/day, duration at least 1 week before testing). These nine patients had a routine screening test at 27 to 28 weeks and then were restudied after being placed on a regimen of terbutaline. The median interval between tests was 2.3 weeks (range 1.1 to 4.2 weeks). As illustrated in Fig. 2, each patient experienced a rise in the 1-hour screening glucose value. The mean 1-hour plasma glu-

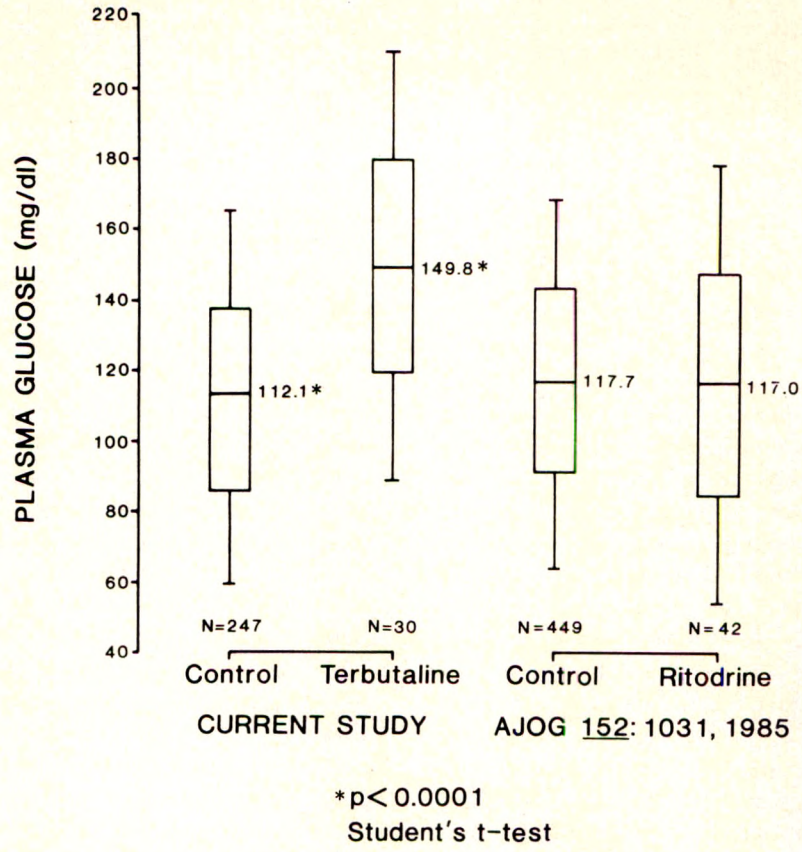

Fig. 1. Screening test results 1 hour after 50 gm of glucose in control and terbutaline-treated patients (mean ± 1 and 2 SD). Our previous results[3] with control and ritodrine patients are illustrated on the right (also mean ± 1 and 2 SD).

Table III. Infant size

	$p = 0.14$*	

*Student's t test.

†Calculated by dividing the measured birth weight by the fiftieth percentile of birth weight (derived from a normal curve for patients in Philadelphia[6]).

cose level before terbutaline was 102.2 ± 36.1 while the mean value during terbutaline therapy was 145.2 ± 25.4 ($p < 0.0001$) (paired *t* test). Two of the nine women had abnormal glucose screening results before terbutaline therapy, but both had a normal 3-hour glucose tolerance test thereafter. After the initiation of terbutaline, results of five of nine glucose screening tests became abnormal and two of these women exhibited gestational diabetes on the 3-hour oral glucose tolerance test. These results are similar to those of the larger group.

We also assessed whether chronic terbutaline therapy was associated with larger birth weights (Table III). This analysis is complicated by the fact that terbutaline was used because the patients had experienced preterm labor and hence were at greater risk for preterm birth. Indeed the mean gestational age in the terbutaline group was 2.1 weeks less than that of the control women (37.0 ± 1.9 versus 39.1 ± 1.6 weeks). The mean birth weight was 240 gm less, a somewhat smaller difference than might be expected for this gestational age difference. Therefore we corrected for gestational age by using the birth weight index. With this correction, there was a tendency toward bigger babies in the terbutaline group but this did not reach statistical significance ($p = 0.14$).

Comment

In our two studies of long-term oral tocolytic therapy, we have noted a clear difference in the effects of terbutaline and ritodrine on glucose tolerance during pregnancy. This is not without precedent. Caritis et al.[7] compared intravenous ritodrine and terbutaline in a

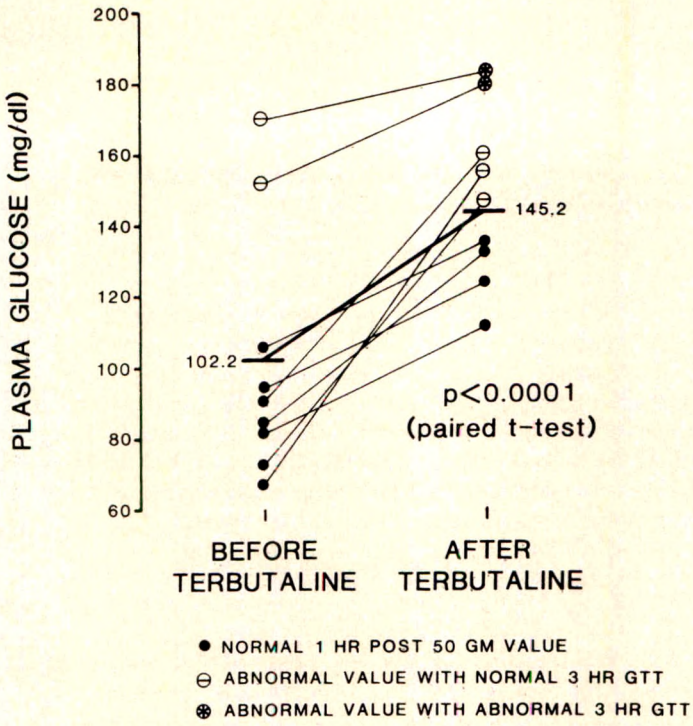

Fig. 2. Results of glucose tolerance testing in nine patients before and during oral terbutaline therapy.

randomized blinded trial. They noted that patients receiving terbutaline had a significantly greater chance of developing hyperglycemia than those receiving ritodrine.

Why should there be a difference between terbutaline and ritodrine? First, terbutaline appears to be a less selective β_2-adrenergic receptor agonist than ritodrine. Second, different tissues may have different sensitivities to various β-sympathomimetics. Which of these or other mechanisms is important for glucose tolerance during pregnancy remains to be determined by more intensive study.

While we could not detect any clinical differences between terbutaline and control groups in terms of outcomes this would not be expected with our study design. All patients were screened and, if appropriate, treated. Thus the natural history and consequences of maternal hyperglycemia were not apparent in this investigation.

As our sample size is small, we can be less certain as to the actual magnitude of the effect of terbutaline on glucose tolerance. However, from our data analysis (odds ratio and confidence intervals) we would expect that there is a 95% likelihood that a minimum of approximately 40% of patients receiving terbutaline will have abnormal 1-hour 50 gm glucose screens with at least a proportionate increase in gestational diabetes. These findings indicate that all pregnant patients receiving long-term terbutaline therapy should undergo screening for glucose intolerance at least once after 7 days of terbutaline therapy. Furthermore, these results underscore the need for careful assessment of the potential risks and benefits of long-term oral tocolytic therapy.

Fetal echocardiographic screening for congenital heart disease: The importance of the four-chamber view

Joshua A. Copel, M.D.,* Gianluigi Pilu, M.D., Jacqueline Green, M.S., R.D.M.S., John C. Hobbins, M.D., and Charles S. Kleinman, M.D.**

New Haven, Connecticut

The four-chamber view of the heart has been proposed as a screening method for obstetrical sonographers to assess the fetus for the presence of congenital heart disease. We examined the fetuses in 1022 pregnancies and found 74 structurally abnormal hearts. Seventy-one of these (96%) were found to have an abnormality as seen in the four-chamber view. The four-chamber view of the heart had 92% sensitivity and 99.7% specificity in the detection of congenital heart disease. The positive predictive value was 95.8%, and the negative predictive value was 99.4%. We conclude that the four-chamber view may be a useful screen for the presence of congenital heart disease and should be included as a part of all routine obstetric ultrasound examinations. (Am J Obstet Gynecol 1987;157:648-55.)

Key words: Congenital heart disease, ultrasound, fetal diagnosis

Fetal echocardiography is an accurate tool for the prenatal diagnostic evaluation of the fetus at risk for congenital heart disease.[1-5] Pregnancies with any of a number of risk factors should be screened to identify affected fetuses, and the information obtained should be used in the formulation of perinatal and neonatal management plans.[6] Additionally, fetuses with arrhythmias may be evaluated and treatment of certain arrhythmias may be offered based on these techniques for diagnosis[7] and monitoring therapy.[8]

Despite attempts to identify high-risk groups, most neonates with congenital heart disease do not have prenatal risk factors. Thus a method to permit the clinician to screen for congenital heart disease during routine sonographic examinations would be useful. The four-chamber view of the fetal heart has been proposed for this purpose.[9, 10]

We have reported that the incidence of congenital heart disease among fetuses referred for fetal echocardiography due to a suspicion of cardiac abnormality during a routine obstetric scan is 50%.[6] We here present the results of a prospective and retrospective evaluation of the appearance of the four-chamber view in a group of fetuses at high risk of congenital heart disease who were scanned during the second and third trimesters of pregnancy over a 3-year period.

Material and methods

Between January 1, 1984 and December 31, 1986, a total of 1193 fetal echocardiograms were performed on 991 women carrying a total of 1022 fetuses. There were 31 sets of twins, two sets of conjoined twins, and one normal twin with an acardiac, acephalic parasitic co-twin. Indications for examination (Table I) were in accordance with previously identified selection criteria that placed the mothers at risk for carrying fetuses with heart disease.[11] Gestational ages at the time of diagnosis varied from 18 weeks to term.

All patients underwent a detailed biometric examination followed by fetal echocardiography with 5 mHz sector scanners (Hewlett-Packard Model 77020A, Andover, MA; Advanced Technologies Laboratories model MK600, Bellvue, WA; Technicare model 256, New Brunswick, NJ). Fetal echocardiographic examinations consisted of standard tomographic views (four-chamber, short axis of the ventricles and great vessels, long axis of the left ventricle, aortic arch, and ductus)[11] for all patients. Pulsed Doppler examinations were carried out on selected patients for the evaluation of dysrhythmias and valvular competence with equipment calibrated by the manufacturers to comply with applicable Food and Drug Administration acoustic output limitations (model MK 600 and UltraMark 4, Advanced Technologies Laboratories; model RT 3600, General Electric, Milwaukee, Wisconsin).

All structural diagnoses were based on the appearance of the heart on two-dimensional scan. M-Mode

echocardiography was used only for the evaluation of rhythm disturbances. All scans were performed and/or reviewed by at least two physicians experienced in fetal cardiac ultrasound. Scans were recorded on videotape for later review. Follow-up information was obtained from clinical or autopsy records from Yale-New Haven Medical Center or by contacting the referring physicians.

The four-chamber view of the heart was obtained as the initial step of each fetal echocardiogram. The abdominal circumference was visualized and the transducer was directed toward the fetal head. The four-chamber view was considered to be normal if the two atria and two ventricles were equal to each other in size and contractility, and if none of the abnormal criteria were present (Fig. 1). The four-chamber view of the heart was considered to be abnormal if any of the following were present: ventricular disproportion, myocardial hypertrophy, dilation or hypoplasia of any of the chambers, septal defects other than the presence of the foramen ovale, or obvious deformities of the atrioventricular valves. These assessments were based on an evaluation of the two-dimensional scan, and not on M-mode measurements.

Table II. Lesions identified

Lesion	No.	Abnormal four-chamber view	
		n	%
Complete atrioventricular septal defect	16	16/16	100
Hypoplastic left heart syndrome	8	8/8	100
Ventricular septal defect	7	5/7	71

True negative	944
Sensitivity	69/75 = 92%
Specificity	944/947 = 99.7%
Positive predictive value	69/72 = 95.8%
Negative predictive value	944/950 = 99.4%

Results

A total of 74 cardiac anomalies were identified. Table I demonstrates the diagnostic groups from which these patients originated. Hypertrophic cardiomyopathy among fetuses of mothers with diabetes is not included in these data. Pericardial effusions in patients with nonimmune hydrops fetalis and otherwise structurally normal hearts are also not included.

Follow-up data have been obtained on all fetuses suspected to have cardiac anomalies. The prenatal cardiac diagnosis was correct in all but nine cases. There were five false negative and four false positive diagnoses. In several of the false positive diagnoses, the four-chamber view of the heart was normal.

False negative results. One fetus had an apparently normal heart at 21 weeks' gestation, but was found at birth to have right ventricular inflow obstruction, right ventricular hypoplasia, and right-to-left atrial shunting. The right ventricular inflow obstruction was attributed to a neoplasm of the tricuspid valve. Review of the prenatal and postnatal echocardiograms suggested that the lesion had been acquired between 20 and 40 weeks' gestation.

A fetus scanned at 29 weeks because of a fetal arrhythmia and found to have atrial extrasystole was diagnosed after delivery to have transposition of the great vessels. Review of the scan demonstrated suboptimal visualization of the great vessels and normal four-chamber anatomy.

Another fetus scanned at 19 weeks due to a fetal arrhythmia (determined to be atrial extrasystole) was found to have coarctation of the aorta after delivery. Review of the prenatal scan confirmed the normal appearance of the four-chamber view of the heart.

A woman with White Class D diabetes, in good control through the first trimester (hemoglobin A_{1c} <6 gm %), was scanned at 18 weeks' gestation. Although the scan was read as normal at the time, the neonate was cyanotic, and a postnatal echocardiogram demonstrated complete transposition of the great arteries. Review of the prenatal scan confirmed a normal four-chamber view, with poor visualization of the great arterial courses.

The final false negative diagnosis occurred in a patient scanned at 20 weeks because of maternal tetralogy of Fallot. She had undergone surgical repair in childhood and was not cyanotic. Despite a normal fetal echocardiogram, pulmonic stenosis and a perimembranous ventricular septal defect were detected at birth. Retrospective review of the echocardiogram confirmed the abnormal appearance of the heart, including an abnormal four-chamber view demonstrating ventricular disproportion.

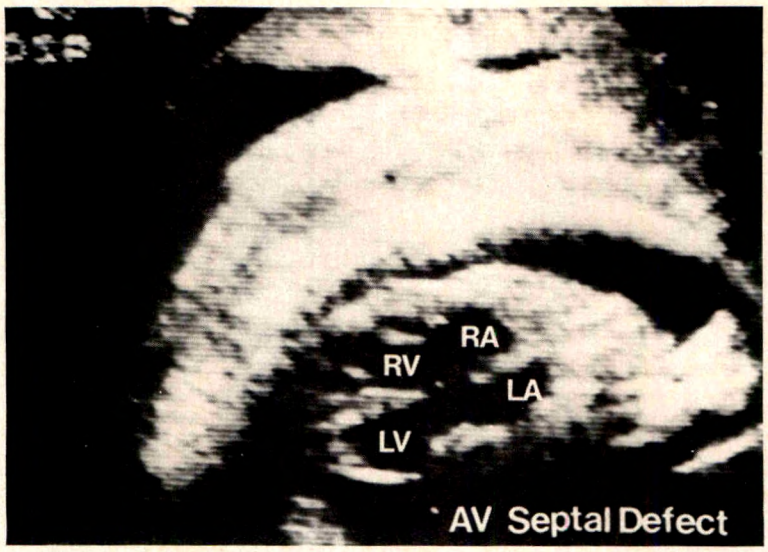

Fig. 2. Four-chamber view of heart with complete atrioventricular septal defect. The large defect between the atria and ventricles is readily apparent. A large pleural effusion is also present. *LA* = Left atrium; *RA* = right atrium; *LV* = left ventricle; *RV* = right ventricle.

False positive results. A fetus scanned at 19 weeks for partial trisomy 7 was suspected to have a coarctation of the aorta, based on ventricular disproportion (right ventricular dilation). Although the great vessels were normal on postmortem examination, right ventricular hypertrophy was confirmed.

Another fetus was scanned at term because of a "fetal heart murmur," with a ventricular septal defect suspected from a scan at another institution. The interventricular septum appeared to be intact, but the aorta was extremely tortuous, and an aortic arch anomaly was suspected because of the apparent redundancy of the vessel. After delivery, echocardiography demonstrated a normal heart with a tortuous, but otherwise normal, aorta. The four-chamber view, however, was normal.

A fetus scanned at 26 weeks because of polyhydramnios and a suspicious appearance of the heart during obstetric evaluation of the amniotic fluid was suspected to have subaortic stenosis. The polyhydramnios progressed to oligohydramnios with intrauterine growth retardation. Amniocentesis revealed Klinefelter syndrome (47,XXY). Continuing echocardiographic examination results did not change. Postnatal echocardiography demonstrated an elongated left ventricular outflow tract, with no stenosis.

The final false positive study was in a fetus scanned at 21 weeks before elective termination for Down syndrome. The four-chamber view was abnormal because of biventricular dilation, and evaluation of the outflow tracts suggested overriding aorta. Results of postmortem examination of the heart were normal.

Determination of congenital heart disease. Table II summarizes the cases of congenital heart disease encountered during the course of this investigation. Seventy-one of the 74 (96%) fetuses identified to have congenital heart disease had abnormalities potentially detectable in the four-chamber view of the heart. In some cases the anatomic defect could not be completely delineated from the four-chamber view alone. For example, severe pulmonic stenosis (encountered in two fetuses) caused dilation of the right ventricle and atrium in each. Further assessment, including two-dimensional views of the right ventricular outflow tract and pulsed Doppler flow studies, clarified the diagnosis.

The false negative and false positive diagnoses that occurred are summarized in Table III. The diagnostic utility of the four-chamber view is analyzed in Table IV. For the latter, only the pathologically proved cases of congenital heart disease are considered.

Although pericardial effusions in hydropic fetuses were excluded from study, two patients with final diagnoses of isolated pericardial effusion are included. One was referred because of hydrocephalus and later underwent amniocentesis, revealing a ring chromosome 13. Except for pericardial effusion, the heart was normal at autopsy. The other was referred because of an abnormal four-chamber view of the heart, with an isolated pericardial effusion noted at 22 weeks. This resolved over the next several weeks, and at 28 weeks hydrocephalus was noted. Congenital viral infection was diagnosed in the neonatal period based on hydrocephaly and periventricular calcifications. Neonatal serology studies were not diagnostic.

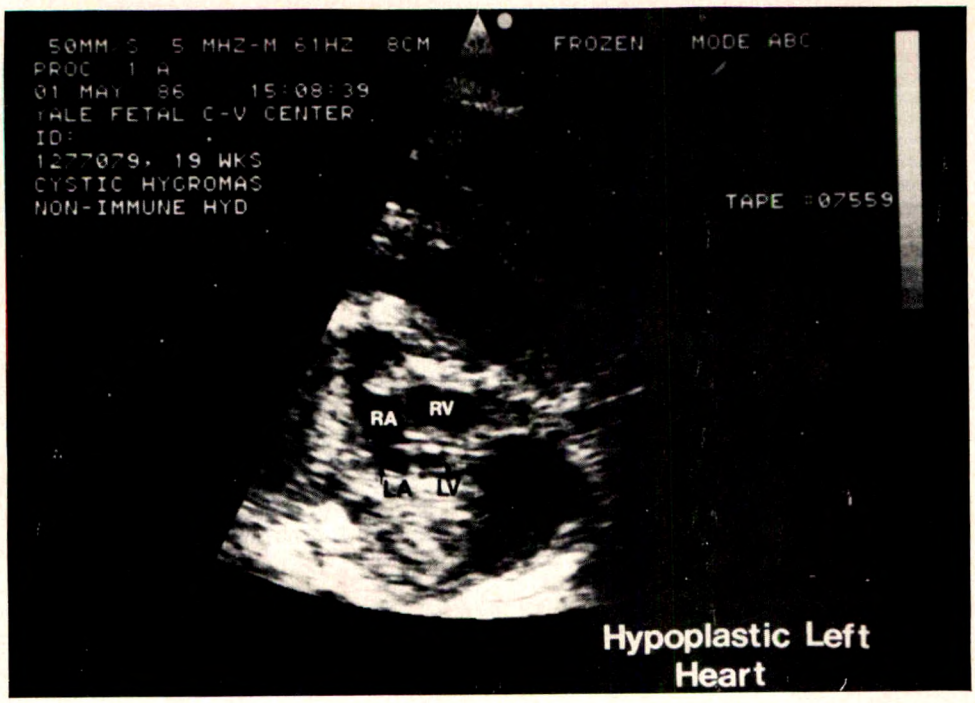

Fig. 3. Four-chamber view of the heart with hypoplastic left heart syndrome. The fetus presented with nonimmune hydrops and cystic hygromas at 19 weeks. Karyotype confirmed Turner syndrome (45,X).

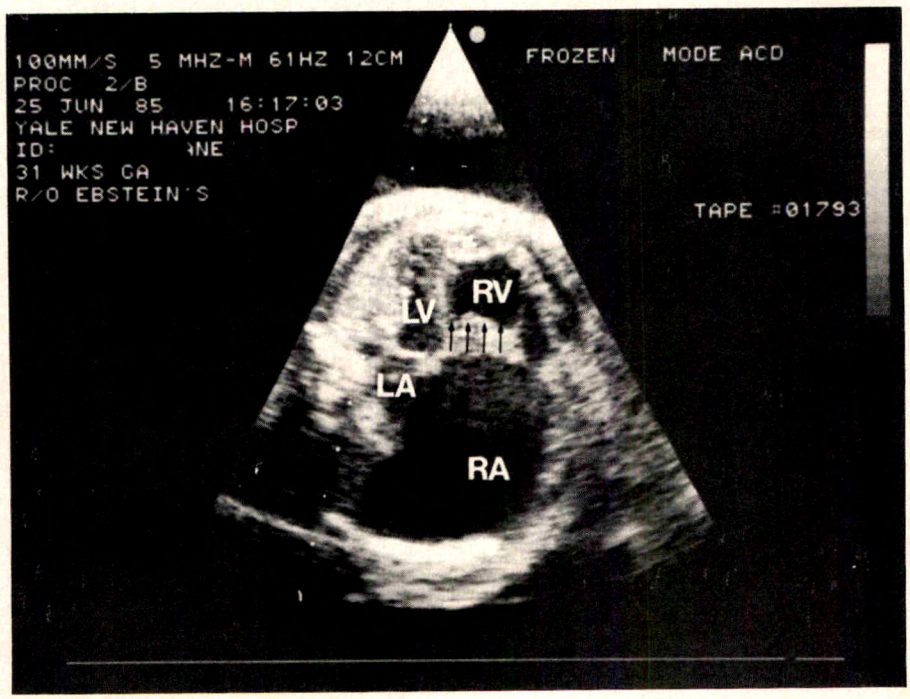

Fig. 4. Four-chamber view of a heart with Ebstein malformation of the tricuspid valve. There was no history of lithium exposure. The right atrium *(RA)* is greatly enlarged, with a much smaller left atrium *(LA)* adjacent to it. The malformed tricuspid valve is shown with small *arrows*. *LV* = Left ventricle; *RV* = right ventricle.

Atrioventricular septal defects (16 cases), hypoplastic left heart syndrome (eight cases), and Ebstein anomaly of the tricuspid valve (five cases) constituted 29 of the 74 anomalies encountered (39%). These were easily diagnosed on the four-chamber view (Figs. 2 to 4).

Comment

The four-chamber view of the heart is relatively easy to obtain during routine obstetric sonography. By tilting the transducer cephalad from the tomographic plane used to measure the abdominal circumference, one brings the four cardiac chambers into view. As such, it is simple to include as a screening view for congenital heart disease, and our experience has suggested that is obtainable in >95% of cases scanned between 18 weeks and term.

We have demonstrated that some abnormality of the four-chamber view of the heart was present in 69 fetuses encountered during the study period who were subsequently found to have congenital heart disease. There are potential problems with our data: (1) The data are drawn from patients referred for fetal echocardiography and thus at high risk for congenital heart disease; (2) we are experienced in fetal echocardiography and thereby particularly sensitized to the need for detailed examination of the heart; (3) although the sensitivity of the four-chamber view of the heart to the presence of congenital heart disease was 92% in this series, the data are insufficient to allow us to comment on the sensitivity of the four-chamber view of the heart when performed as part of a "level I" scan by less experienced fetal cardiac sonographers.

The sensitivity of the four-chamber view to the presence of congenital heart disease was not perfect. This has been the experience of other centers as well.[12] The lesions detected with a high degree of sensitivity are those that are expected to distort the four-chamber anatomy. We are less confident in our ability to detect lesions that do not affect that view. This point is important, because a screening four-chamber view cannot be offered to patients as a means of ruling-out all forms of congenital heart disease. Rather, it is an effective screen for many of the more severe forms of congenital heart disease, for which the prognosis might be improved by controlled delivery at a center equipped to manage the neonate. The ability of a four-chamber view to exclude congenital heart disease is attested to by the high negative predictive value of the test (99.4%).

It is of interest that 20 of 40 (50%) patients referred because of a suspicious level I scan were found by fetal echocardiography to have congenital heart disease, suggesting a relatively high specificity. This may be compared with an incidence of 5.5% (54/982) among fetuses referred for all other indications and is consistent with our previous preliminary report[6] of a portion of the patients reported upon here, in which a 50% incidence of congenital heart disease was found among such patients. Allan et al.[10] have noted a similar increase in the proportion of referrals because of suspected abnormalities in screening ultrasound studies. Preliminary data from a prospective study involving screening four-chamber views of the heart suggest that a large proportion of structural cardiac disease may be detected in utero.[12]

We have intentionally not used M-mode measurements of the heart because they are more difficult to obtain and require specialized training to apply accurately. We have found, moreover, that the orientation of the fetal heart is often not conducive to cursor placement for such measurements. In choosing to evaluate our data based on subjective criteria, we were attempting to use a more widely applicable standard, recognizing that the experience of the sonologist will play a part in any such criteria.

Table V. Proposed indications for fetal echocardiography

Fetal risk factors
Extracardiac anomalies
Chromosomal
Anatomic
Fetal cardiac arrhythmia
Irregular rhythm
Tachycardia (>200 bpm)
Bradycardia (nonperiodic)
Nonimmune hydrops fetalis
Suspected cardiac anomaly on level I scan
Maternal risk factors
Congenital heart disease
Cardiac teratogen exposure
Lithium carbonate
Progestins
Amphetamines
Alcohol
Anticonvulsants
Phenytoin
Trimethadione
Isotretinoin
Maternal metabolic disorders
Diabetes mellitus
Phenylketonuria
Polyhydramnios
Maternal infections
Rubella
Toxoplasmosis
Coxsackie virus
Cytomegalovirus
Mumps
Familial risk factors
Congenital heart disease
Previous sibling
Paternal
Syndromes
Noonan
Tuberous sclerosis

Certain types of congenital heart disease can be anticipated not to cause abnormalities of the fetal four-chamber view. These would include simple small perimembranous or muscular ventricular septal defects and simple transposition of the great arteries. These lesions are frequently accompanied by other intracardiac abnormalities that might cause abnormalities of the four-chamber view.[13, 14] While coarctation of the aorta may be found in association with disproportionate right ventricular dilation, reflecting altered fetal flow patterns, it is not clear whether this is seen in early gestation. Our experience has also suggested that right ventricular dilation may be found in a variety of pathologic states, and that direct identification of a "shelf" of obstructing aortic tissue may be difficult, if not impossible in utero.

High-risk gravid women should still undergo more detailed fetal echocardiographic examinations with multiple overlapping tomographic views to maximize the identification of structural abnormalities, even if the four-chamber view is normal. Because the technology involved in obtaining a detailed complete fetal echocardiographic study is complex and expensive and precise diagnosis requires specialized knowledge of congenital cardiac malformations, certain indications have been suggested to target populations at particular risk of congenital heart disease. The overall population risk of a neonate having congenital heart disease is 0.8%.[15] If a previous sibling has been born with congenital heart disease, however, this rises to 2% to 3%,[16] and if the mother herself has congenital heart disease, the risk may be as high as 10% for her offspring.[17] Other identified risk groups are listed in Table V. For those pregnancies at high risk of congenital heart disease based on any of these factors, complete detailed fetal echocardiography should continue to be offered.

The distribution of indications for sonography (Table II) should not be taken as representative of the general obstetric population, but rather as a reflection of the referral patterns to our institution. Some patients fell into more than one group, such as patients referred for a suspicious screening examination who were then found to have hydrops, or patients found to have chromosomal abnormalities after the cardiac evaluation. In these situations, only the original referral indication is listed. For this reason, Table II cannot be used to estimate the prevalence of such conditions among patients with cardiac anomalies, or the frequency of cardiac abnormalities among all patients with the conditions.

Similarly, the distribution of cardiac diagnoses differs from that found in pediatric series.[18] This may be due to a number of factors, but probably reflects a bias of the technique toward the identification of lesions altering the four-chamber anatomy. It also suggests that many of the fetuses identified antenatally may not survive to the point of inclusion in pediatric series.

We conclude on the basis of our 36-month survey that a carefully performed level I obstetric ultrasound scan should include a four-chamber view of the fetal heart. The sensitivity of such a scan for the detection of congenital heart disease will not be perfect, with anticipated weaknesses including a lack of detection of uncomplicated ventricular septal defects, mild semilunar valve stenoses, aortic coarctation, and simple transposition. However, it can be used to detect anomalies that directly affect the structure of the atrioventricular junction, such as atrioventricular septal defects or Ebstein malformation of the tricuspid valve. In addition, lesions imparting ventricular hypoplasia should be readily identified, especially if these anomalies are associated with atrioventricular valve atresia. Other lesions that cause a greater than normal disparity in ventricular dimensions (e.g., severe semilunar obstruction and/or semilunar or atrioventricular valve insufficiency) or pericardial effusions should be easily identified on such scans.

Our experience has suggested that including a view of the fetal heart in the level I scan will improve the identification of fetuses with congenital heart disease. While it cannot replace the detailed echocardiogram for the fetus at high risk for congenital heart disease, routine application of this simple additional view in the basic ultrasound examination should help to decrease the incidence of undetected congenital heart disease at birth. The sensitivity and specificity we report reflects in part the prevalence of disease in the population under study. Confirmation of these results must be obtained from further prospective studies of the true potential for the use of the four-chamber view as a general screening test. Programs have already been undertaken to implement such screening in Europe and England.[10, 12] Although ultrasonographic examination has not been accepted as a routine part of obstetric care in the United States, a large proportion of prenatal patients are currently scanned. If scans are performed in the second or third trimester of pregnancy, a four-chamber view of the heart should be included. Abnormalities should prompt referral to a facility experienced in detailed evaluation of the structure of the fetal heart.

Ultrasound evaluation of tachycardia-induced hydrops in the fetal lamb

C. Nimrod, M.B., D. Davies, R.D.M.S., J. Harder, M.D., S. Iwanicki, M.D., C. Kondo, A.H.T., Y. Takahashi, A.H.T., J. Maloney, B.Sc., M.Sc., Ph.D., D. Persaud, M.Sc., and S. Nicholson, M.D.

Calgary, Alberta, Canada

Nonimmune hydrops was induced in six fetal lambs at 120 days' gestation by right atrial pacing at 300 beats/min. Biochemical, hemodynamic, and Doppler parameters were observed and monitored by real-time ultrasound during the creation (18 to 42 hours) and resolution of hydrops. The significant changes seen were hypoproteinemia (34.3 to 29.0 mg/100 ml), venous hypertension (24.6 to 31.3 mm Hg), decreases in thoracic aorta flow, and decreases in systolic/diastolic ratios in the aorta and umbilical artery. These changes were reversed with the discontinuation of pacing and the resolution of fetal hydrops. (Am J Obstet Gynecol 1987;157:655-9.)

Key words: Pacing-induced hydrops, fetal tachycardia

Cardiovascular disease has been implicated as a significant cause of nonimmune fetal hydrops.[1] Within this group of disorders supraventricular tachycardia has come into greater focus, because it is amenable to maternal administration of antiarrhythmic drugs.[2, 3] As a result there is a need for a clearer understanding of the natural history and the changes that occur during the evolution of nonimmune hydrops. Prenatal diagnosis of hydrops by ultrasound has been well established in the human fetus.[4] However, investigators working with the fetal lamb hydrops model have been able to assess this condition only at autopsy.[5]

This study assessed the real-time and Doppler ultrasound changes that occurred during the production and resolution of fetal hydrops caused by right atrial pacing.

Methods

Preparation. Six pregnant ewes and their fetuses at approximately 115 days' gestation (term is 143 days) were surgically instrumented and studied. Each ewe was anesthetized by an intravenous injection of 5% sodium thiopental. After they were intubated anesthesia was maintained with a halothane-oxygen mixture. Under sterile surgical technique, the uterus was exposed via a midline incision and the fetal head and chest were exposed. An incision was made in the fourth intercostal space from the right side to expose the heart, and the pericardial sac was opened. The great vessels were identified, and bipolar pacemaker electrodes were implanted in the right atrial appendage close to the insertion of the superior vena cava. The pericardium was left open when the chest was closed. Electrocardiographic electrodes were implanted under the skin of the fetus, with one lead placed in the neck and the other lead placed in the chest wall at the sixth rib.

Fetal femoral artery and jugular venous catheterization was performed. The lost amniotic fluid was replaced by sterile saline, and the uterine incision was closed. The catheter and leads were exteriorized through the ewe's flank before the midline skin incision was closed. Prophylactic antibiotics were administered, and the animals were allowed to recover from the anesthesia. Experiments took place after a minimum recovery period of 4 days.

Experimental protocol. All control and experimental studies were conducted while the ewe was awake and lying restrained on a specially constructed, cushioned table. Between study times the animals were allowed mobility with normal food and water. Baseline biochemical and cardiovascular data were obtained during a control period when measurements were allowed to stabilize for at least 30 minutes. The fetal pacemaker leads were attached to a General Electric Standby Pacemaker 7118 (General Electric, Fairfield, Connecticut), and pacing occurred at 300 beats/min from a mean baseline of 178 beats/min. Pulsed Doppler studies were done during periods of absent fetal breathing by use of a Toshiba 3.5 MHz linear-array transducer combined with a 2.42 MHz fixed-angle pulsed Doppler system with a 100 Hz thump filter. The fetal descending thoracic aorta, umbilical artery, and inferior vena cava were studied. The ultrasound machine provided online calculations of flow velocity and volume flow from the descending aorta. The peak systolic and end-diastolic velocities and systolic/diastolic ratios of the fetal aorta and umbilical artery were calculated by off-line averaging of the measurements from three consecutive waveforms.

After baseline biochemical and ultrasound parameters were measured, pacing was commenced. After the first 12 hours of pacing, real-time ultrasound and blood sampling for biochemical analysis were repeated at ap-

Table II. Age, duration of pacing, and resolution time in six fetal lambs

proximately 4-hour intervals until the ultrasound confirmation of fetal hydrops was made. Hydrops was considered to be present when marked fetal ascites was present with a rim of fluid greater than 1 cm all around the abdomen. This was much easier to recognize and quantitate than pleural effusion or skin edema, and hence it was the only criterion used.

For the purpose of analysis data were presented at the following intervals: (1) before pacing commenced, (2) at the ultrasound diagnosis of fetal hydrops, (3) immediately after pacing was discontinued, (4) during recovery at 12 to 16 hours after pacing was discontinued, and (5) at resolution of fetal hydrops (no ascites or pleural effusion visible on ultrasound).

The ewe was removed from the cushioned table to a metabolic cage after each evaluation. Statistical analysis of data was done with a paired *t* test for grouped results.

Results

Each of the six animals was considered to be normal on the basis of the baseline blood gases, electrolytes, blood pressure, and mean heart rates at the commencement of each study. Table I highlights these baseline values and the biochemical changes seen with the development and clearance of fetal hydrops. There was no statistically significant change in sodium and potassium concentration during development of fetal hydrops. P_{O_2} and P_{CO_2} and pH changes also were not significant. Normal P_{O_2} in our laboratory, which is 4000 feet above sea level, was 23.3 ± 2.6 mm Hg. However, a statistically significant change was seen in serum protein and albumin levels. With right atrial pacing at 300 beats/min it was possible to achieve hydrops between 18 and 41 hours (Table II). Spontaneous resolution of hydrops occurred in each lamb after systolic-diastolic pacing was discontinued.

The changes in mean systolic/diastolic ratio from baseline in the descending thoracic aorta and umbilical artery for the six lambs are summarized in Fig. 1. There was a significant decrease in systolic/diastolic ratio from baseline at the time hydrops developed. Both vessels showed a significant increase in systolic/diastolic ratio immediately after pacing was withdrawn with hydrops still present. Even though the data are presented as mean values, the Doppler changes described above were seen in each fetal lamb studied.

Fig. 2 illustrates the individual changes that occurred in mean aortic velocity and volume flow throughout the experiments. The trends were similar to those described for systolic/diastolic ratio. All animals studied demonstrated a fall in both parameters during the development of hydrops by pacing and an immediate rise when the effect of pacing was removed. In ewe No. 4 the fetal position precluded obtaining any quantitative information from the aorta, and in ewe No. 6 volume flow information is not presented, because it was unobtainable at several of the time intervals studied.

Table III summarizes the changes observed in fetal blood pressure during the study. There was a statistically significant decrease in systolic blood pressure and an increase in venous pressure with the development of hydrops. Both systolic and venous pressures returned to the prepacing levels during the recovery phase.

The normal flow velocity waveform of the inferior vena cava is biphasic, with the larger peak indicative of the systolic-to-diastolic surge[6] (Fig. 3). This relationship is disturbed during pacing in that (1) the biphasic pattern no longer exists and (2) reverse flow in the inferior vena cava is an early change.

After pacing is discontinued the systolic and diastolic surges reappear, reverse flow is no longer apparent, and by 6 hours the normal relationship of the systolic-to-diastolic surge is restored.

Comment

The atrial tachycardia model for the investigation of fetal hydrops was first described by Stevens et al.[5] Ultrasound imaging was not utilized in these experiments, and the presence of hydrops had to be confirmed at autopsy. The improvements in this study include (1) the tachycardia was directly visualized in order to ensure that it was continuous, (2) the time taken for the production and clearance of hydrops was more precisely defined, (3) Doppler blood flow evaluation could

be performed, and (4) the need for prolonged pacing, possibly leading to death, was eliminated.

The pathogenesis of fetal hydrops is not known, but it is postulated that venous hypertension leads to loss of albumin into the extravascular space, with the resultant decreased osmotic and increased venous pressure combining to produce hydrops.[3] Our results agree with this postulate. Because of the obvious difficulty of continuous monitoring of the sheep, our study does not answer the question of the natural progression of changes seen during the production of hydrops. However, ascites was seen first and then became more severe along with the development of pleural effusions and abdominal wall edema. Our studies were performed with right atrial pacing only; it has previously been noted in animal studies that pacing of an atrium results in a decrease in the ipsilateral ventricular output. Therefore, with right atrial pacing a decrease in flow

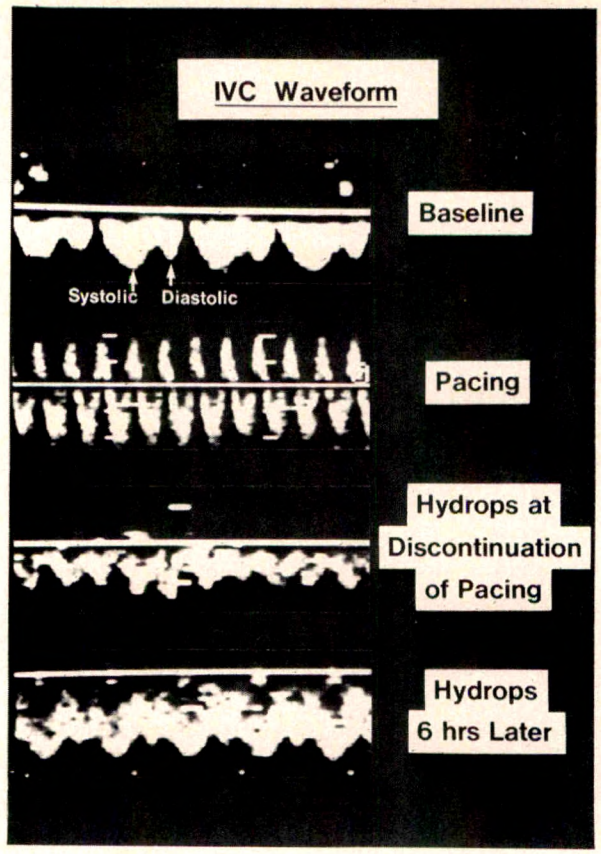

Fig. 3. The inferior vena cava *(IVC)* waveform under different experimental conditions.

in the descending thoracic aorta would be anticipated; this in fact was our observation (Fig. 2). When pacing was discontinued a prompt and significant increase in velocity and volume flow occurred. The immediate improvement after pacing would support the fact that the fetal myocardium was not dysfunctional, although our study did not specifically evaluate myocardial ischemia and function. Other investigators working with an isoproterenol-induced tachycardia have shown the preservation of intramyocardial blood flow during pacing but a decrease in myocardial glycogen.[7] The Doppler changes seen at the time of fetal hydrops are a summation of changes caused by tachycardia and those secondary to hydrops. In a limited number of animals (four) umbilical systolic/diastolic ratio was recorded at 16 hours after pacing was initiated, but before hydrops developed. In each of these the umbilical systolic/diastolic ratio was significantly lower than baseline values. In all animals the systolic/diastolic ratio found immediately on discontinuation of pacing with hydrops present was also significantly different from baseline values.

These Doppler studies add new information on changes in venous and arterial flow patterns in the hydropic animal model. The changes noted in the pressure and flow in the inferior vena cava concur with the

observations of Reuss et al.[8] A trend in our data suggests that an inverse correlation exists between the baseline venous pressure and the time to development of hydrops. Statistical significance was, however, not achieved. During the recovery phase after pacing the normal biphasic pattern of flow in the inferior vena cava with a predominant systolic peak, was rapidly established.

The Doppler waveform in the descending aorta and umbilical artery showed a significant decrease in systolic/diastolic ratio in all animals during hydrops. This was complemented by a decrease in both volume flow and velocity in the aorta. Prompt increases in all of these measurements after pacing was terminated are the observed features of the recovery phase of hydrops.

The design of our study differed from that of Stevens et al.[5] in that their period of pacing was much longer (72 to 216 hours) and several of their animals (six) died during pacing. It is not surprising therefore that even though the baseline levels of PaO_2 were low but similar in both studies, a greater decrease was seen after pacing by Stevens et al. We recognize that the baseline PaO_2 levels were lower than expected; however, none of our animals died during the experimental or recovery period or were otherwise compromised.

Our studies also demonstrated decreases in serum protein and albumin at the time of development of hydrops and return to baseline levels in the recovery period. These changes were not seen by Stevens et al., and one can only speculate that this was probably due to the more chronic nature of their preparation.

In summary, in this study of an animal model of fetal hydrops produced by rapid atrial pacing, we have observed venous hypertension, a drop in serum protein, and an alteration in the venous flow pattern but no significant change in fetal blood gases. The aortic velocity and volume flow during tachycardia-induced hydrops were decreased but showed a prompt increase after pacing was terminated; this increase continued during the recovery phase. The systolic/diastolic ratio was consistently decreased during pacing and at development of hydrops and also was observed to rise again during the recovery period. The Doppler analysis of flow in the fetal vessels has provided new and important information on the fetal changes during tachycardia-induced hydrops and fetal recovery.

Digoxin-like immunoreactive substance in pregnancy

Antonio R. González, M.D., Stephanie J. Phelps, Pharm.D., Emily B. Cochran, Pharm.D., and Baha M. Sibai, M.D.

Memphis, Tennessee

Our aims were to determine the potential usefulness of digoxin-like immunoreactive substances in the prediction of preeclampsia, to study the relationship between fetal production of these substances and maternal serum levels, and to evaluate the association between digoxin-like immunoreactive substances and plasma volume findings in preeclamptic pregnancies. Serum digoxin-like immunoreactive substance concentrations were measured in normotensive and preeclamptic pregnant women and in umbilical artery and vein blood samples. None of the patients in the first trimester (n = 53) and 11% of those in the second (n = 56) had detectable levels of this substance. However, 91% of the patients in the third trimester (n = 161) had positive results. The concentrations of digoxin-like immunoreactive substances in the preeclamptic group (n = 78) were significantly ($p < 0.005$) lower than those of third-trimester (n = 83) normotensive patients (0.22 ± 0.12 versus 0.32 ± 0.15 ng/ml). However, there were no significant differences between the two groups regarding digoxin-like immunoreactive substance concentrations when matched for gestational age (41 patients in each group). Digoxin-like immunoreactive substance concentrations in umbilical vessels were significantly higher ($p < 0.001$) than the corresponding maternal levels. Umbilical vessel digoxin-like immunoreactive substance levels demonstrated good correlation with fetal gestational age and birth weight in both normotensive and preeclamptic pregnancies. On the other hand, there was a poor ($r = 0.02$; $p = 0.91$) correlation between plasma volume findings and digoxin-like immunoreactive substance concentration. We conclude that the digoxin-like immunoreactive substance level may be of very little value in the prediction of preeclampsia. The presence of digoxin-like immunoreactive substance at greater concentrations in the umbilical cord blood samples suggests the possibility of the fetus as the source of this substance. Digoxin-like immunoreactive substances may not play a major role in plasma volume expansion during pregnancy. (Am J Obstet Gynecol 1987;157:660-4.)

Key words: Pregnancy, preeclampsia, digoxin-like immunoreactive substance

Endogenous digoxin-like immunoreactive substances that cross react with commercially available digoxin assays have been described by several authors.[1] The presence of this substance has led to falsely elevated digoxin concentrations in patients treated with this drug, as well as measurable levels in others who have never received digitalis glycosides. In addition, digoxin-like immunoreactive substances have been found in varying degrees in persons who suffer from chronic renal failure, hepatic disease, and chronic hypertension.[1, 2] These substances have also been detected in experimental animals submitted to acute volume expansion and salt loading.[3, 4] Furthermore, digoxin-like immunoreactive substances have been found to be present in varying concentrations during pregnancy,[1, 5-7] in amniotic fluid,[1, 8, 9] and in fetal and neonatal serum.[9-11] Some studies have suggested that the concentration of digoxin-like immunoreactive substances in the serum of preeclamptic patients is significantly higher than that in normotensive pregnant patients.[5-7, 9, 12, 13] To date, the exact structures of these substances have not been clearly defined, but research has been conducted in terms of their physiologic activity. Digoxin-like immunoreactive substances are natriuretic and produce vasoconstriction.[4] They also inhibit ionized sodium/ionized potassium adenosine triphosphatase activity.[10]

The aims of this study were threefold: (1) to determine the potential usefulness of digoxin-like immunoreactive substances in the prediction of preeclampsia; (2) to study the relationship between fetal and maternal concentrations of these substances; and (3) to evaluate the association between digoxin-like immunoreactive substances and plasma volume findings in preeclamptic pregnancies.

Material and methods

Blood samples were collected from normotensive pregnant women in the first (n = 53), second (n = 56), and third (n = 83) trimesters. None of the patients suffered from chronic hypertension and none had

Table I. Concentrations of digoxin-like immunoreactive substances by trimester

Trimester	*Concentration (ng/ml)*		*% Positive*
	Mean ± SD	*Range*	
First (n = 53)	0	0	0
Second (n = 56)	0.02 ± 0.07	0-0.47	11
Third (n = 161)	0.27 ± 0.15	0-0.93	91
Preeclamptic (n = 78)	0.22 ± 0.12	0-0.58	86
Normotensive (n = 83)	0.32 ± 0.15	0-0.93	95

taken digoxin before the study. Specimens were also obtained from women in the third trimester (n = 78) who met standard criteria for the diagnosis of preeclampsia.[14] In a subgroup of 25 of these patients plasma volume was determined simultaneously with digoxin-like immunoreactive substance measurements. Plasma volume measurements were done according to the Evans blue dye-dilution technique as described previously.[15] At the time of delivery, samples were drawn from the umbilical artery, umbilical vein, and maternal vein (n = 25). Specimens were centrifuged immediately, and the serum was stored at −70° C until analysis (within 30 days of collection). Samples were analyzed in duplicate by the RIANEN digoxin assay (New England Nuclear, North Billerica, Massachusetts). The lower limit of sensitivity of the assay is 0.11 ng/ml, with a coefficient of variation of 6.1% at a concentration of 0.5 ng/ml and 3.6% at 2.5 ng/ml. All values below the lower limit of sensitivity of the assay were considered zero in analysis of data.

Neonatal outcome included gestational age and birth weight. Unless otherwise noted, all data are reported as mean and SD. Data were analyzed by regression analysis and paired and unpaired Student's *t* test. Significance was set at $p < 0.05$.

Results

A total of 270 patients were included in this study. Two hundred forty-five patients were studied antepartum and 25 were studied intrapartum. In the antepartum group, two patients had preeclampsia in the second trimester and 78 had it in the third trimester. The average gestational age at time of sampling was 10.2 ± 1.7 weeks in the first trimester group, 18.5 ± 2.6 weeks in the second-trimester group, and 37.7 ± 3.7 weeks in the third-trimester group. Simultaneous samples from mother and umbilical vessels were obtained in 25 patients admitted in labor; six of them had preeclampsia.

Table I summarizes the distribution of digoxin-like immunoreactive substance concentrations by trimester. None of the patients in the first trimester had measurable digoxin-like immunoreactive substance levels. Only six (11%) of those in the second trimester had detectable levels; one of these developed preeclampsia in the third trimester, while the other five remained normotensive. In contrast, 146 (91%) of third-trimester tests yielded positive results. The mean digoxin-like immunoreactive substance concentrations in third-trimester women with preeclampsia was 0.22 ± 0.12 ng/ml, significantly lower ($p < 0.005$) than the value (0.32 ± 0.15 ng/ml) in normotensive third-trimester patients. However, there was a considerable overlap in concentrations in the two groups.

As can be expected, patients with preeclampsia had significantly higher systolic (145 ± 16.2 versus 121 ± 13.5 mm Hg, $p < 0.0001$) and diastolic (96 ± 13.1 versus 73 ± 11.3 mm Hg; $p < 0.0001$) blood pressures, were delivered earlier in gestation (36.5 ± 3.8 versus 38.9 ± 2.7 weeks; $p < 0.001$), and had lower birth weight babies (2634 ± 684 versus 3069 ± 474 gm; $p < 0.028$). In addition, there were strong correlations between digoxin-like immunoreactive substance concentrations and fetal gestational age ($r = 0.98$; $p < 0.0004$) and birth weight ($r = 0.53$; $p < 0.03$) in normotensive patients. Similar results were observed in the group of women with preeclampsia ($r = 0.73$ [$p = 0.005$] and $r = 0.50$ [$p = 0.01$], respectively).

To correct for differences in gestational age between the two groups, we compared the digoxin-like immunoreactive substance findings in 41 patients matched by gestational age with a similar number of normotensive patients. We found no significant differences in digoxin-like immunoreactive substance concentrations between the two groups.

The distribution of digoxin-like immunoreactive substance values in the mother, umbilical vein, and artery are shown in Fig. 1 as Tukey box plots. The mean digoxin-like immunoreactive substance concentration in cord arterial blood was significantly higher than the mean maternal concentration (0.83 ± 0.46 versus 0.29 ± 0.24 ng/ml; $p < 0.001$). Similar findings were observed between cord venous blood and maternal concentrations (0.79 ± 0.41 versus 0.29 ± 0.24 ng/ml; $p < 0.001$). However, there were no significant differences between cord arterial and venous cord blood

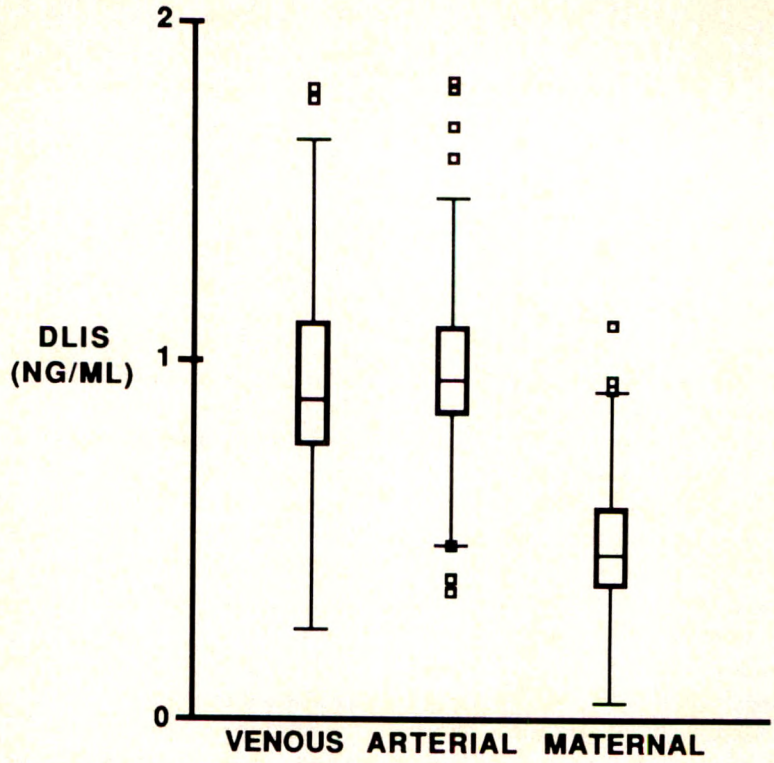

Fig. 1. Umbilical artery, umbilical vein, and maternal digoxin-like immunoreactive substance concentrations *(DLIS)* at the time of delivery. □ Represents valves outside ± SD; □□ indicates median and distribution of 50% of the valves; I shows ±2 SD.

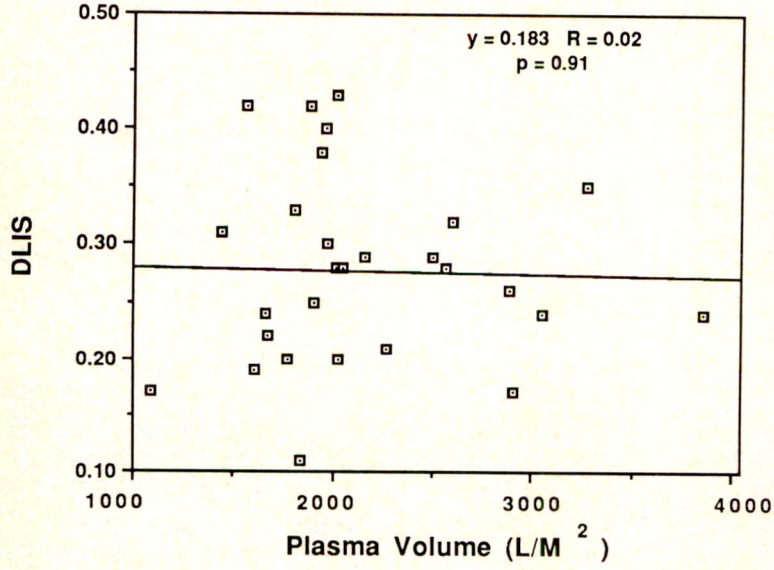

Fig. 2. Correlation between plasma volume findings and digoxin-like immunoreactive substance concentrations *(DLIS)* in preeclamptic pregnancies.

digoxin-like immunoreactive substance concentrations. Moreover, there were good correlations between cord blood digoxin-like immunoreactive substance values and both fetal gestational age ($r = 0.53$; $p < 0.01$) and birth weight ($r = 0.69$; $p < 0.03$).

Fig. 2 correlates digoxin-like immunoreactive substance concentrations to plasma volume findings in the 25 patients studied. It is obvious that there is a poor correlation between these substances and the plasma volume.

Comment

There are several reports describing digoxin-like immunoreactive substance findings during pregnancy. Most previous studies have evaluated serum digoxin-like immunoreactive substance levels during the third trimester.[5, 7] However, Valdes et al.[5] studied digoxin-like immunoreactive substance concentrations in normal pregnancy during the first (n = 11), second (n = 17), and third (n = 20) trimesters. The mean (±SEM) digoxin-like immunoreactive substance concentrations were 0.045 ± 0.01, 0.125 ± 0.03, and 0.195 ± 0.03 ng/ml, respectively. It is apparent from these findings that very few patients had detectable digoxin-like immunoreactive substance concentrations during the first and second trimesters. Our findings are similar to those reported by Valdes et al.

The pathophysiologic mechanisms responsible for the development of preeclampsia are not well understood. Because the physiologic activities of digoxin-like immunoreactive substances include natriuresis, ionized sodium/ionized potassium adenosine triphosphatase inhibition, and peripheral vasoconstriction, some authors have proposed that digoxin-like immunoreactive substance may have an etiologic role in the pathogenesis of preeclampsia. Valdes et al.[5] compared digoxin-like immunoreactive substance concentrations in 22 patients with hypertension in the third trimester with those found in 20 normotensive pregnancies. They found significantly higher values in the hypertensive group. Although their normotensive and hypertensive groups had comparable gestational ages, it is not clear if the patients were matched for gestational age and whether any of the patients with hypertension were chronically hypertensive. Gusdon et al.[7] compared digoxin-like immunoreactive substance concentrations in 10 third-trimester preeclamptic pregnancies with those in 10 normotensive pregnancies in the third trimester. They reported significantly higher values in the preeclamptic group. They speculated that "the increase in blood pressure in preeclampsia is somehow related to increased levels of the natriuretic hormone." It is interesting to note that the average digoxin-like immunoreactive substance concentration (0.14 ± 0.15 ng/ml) in the preeclamptic group in their study was actually lower than the average (0.195 ± 0.03 ng/ml) in the normotensive group described by Valdes et al.

Beyers et al.[6] studied digoxin-like immunoreactive substance concentrations in 36 normotensive and 21 preeclamptic patients at an average gestational age of 38.3 weeks. The average birth weight in both groups was similar, while the average digoxin-like immunoreactive substance concentration was higher in the preeclamptic group (0.68 ± 0.3 versus 0.52 ± 0.06 ng/ml). However, these authors considered all values <0.5 ng/ml to be 0.5 ng/ml, and seven of the preeclamptic patients had preexisting chronic hypertension. More recently, Goodlin[13] reported on 59 patients with expanded toxemia syndrome. Digoxin-like immunoreactive substance levels were measured in 27 patients, with 67% of them having abnormal values (>0.2 ng/ml).

Secombe et al.[9] determined digoxin-like immunoreactive substance concentrations in 36 amniotic fluid samples obtained between 16 and 43 weeks' gestation. They found that the concentration in amniotic fluid was constant from 16 to 33 weeks' gestation but increased after 33 weeks. In the same report, the authors compared digoxin-like immunoreactive substance concentrations in umbilical artery, umbilical vein, and maternal serum samples. There was no difference between umbilical vein and artery concentrations, but umbilical vein concentrations were consistently higher than those in the mother. Their findings suggested that digoxin-like immunoreactive substance was of fetal origin. In a similar report Beyers et al.[6] found mean digoxin-like immunoreactive substance levels to be higher in cord blood than in maternal blood. Our findings regarding cord blood and maternal digoxin-like immunoreactive substance concentrations are in agreement with both of these reports. In addition, we found good correlations between digoxin-like immunoreactive substance values and both fetal gestational age and birth weight. Hence a fetal origin for this substance seems very likely.

We found lower levels of digoxin-like immunoreactive substance in the preeclamptic group than in the normotensive group. However, the preeclamptic group had both lower gestational ages and birth weights. When the two groups were matched for gestational age, we found no differences in digoxin-like immunoreactive substance concentrations between preeclamptic and normotensive pregnancies. In addition, there was considerable overlap in concentrations in the two groups. These findings are in disagreement with those reported previously. The differences in our data as compared with those of others[6, 7, 9, 12, 13] may be due to differences in populations studied, differences in gestational ages, and different methods of extraction of the substance and the assays used. The radioimmunoassay we used (RIANEN) is the same assay used by Valdes et al.,[5] Graves et al.,[12] and as Gusdon et al.[7] However, Gusdon et al. and Beyers et al.[6] used an extraction procedure. Moreover, the radioimmunoassay technique used by Beyers et al.[6] is similar to our technique. However, these investigators considered all values <0.5 ng/ml as an absolute value of 0.5 ng/ml, and seven of the patients with preeclampsia had preexisting chronic hypertension. These factors may account for the observed differences. The reliability of the radioimmunoassay technique in pregnancy has been recently validated by Clerico et al.,[16] who found a significant

correlation between digoxin-like immunoreactive substance values obtained by radioimmunoassay methods and radioreceptor assays for 21 chromatographic extracts of plasma from pregnant women and neonates. These authors stated that the digoxin radioimmunoassay method can be used for digoxin-like immunoreactive substance determinations because it is "more sensitive, precise, and simple than other techniques used to detect endogenous cardiac-glycosides–like compounds." The fluorescence polarization immunoassay used by Goodlin[13] is less specific for digoxin-like immunoreactive substance because it shows cross-reactivity with progesterone, cortisol, and cortisone. The use of this technique could have influenced the results of that study.

Because digoxin-like immunoreactive substances are rarely detected in the first and second trimesters and the concentrations are not elevated in preeclampsia in the third trimester, it is very unlikely that this test will be helpful in predicting preeclampsia.

In normal pregnancy, plasma volume expansion starts very early in the first trimester, reaches a plateau at 24 to 34 weeks' gestation, and is maintained until term.[15] We found a poor correlation between digoxin-like immunoreactive substance concentrations and plasma volume in the preeclamptic subgroup. Additionally, digoxin-like immunoreactive substance was not detected in the first trimester and only 11% of patients had measurable levels in the second trimester. These findings suggest that digoxin-like immunoreactive substance does not play any major role in plasma volume expansion during pregnancy.

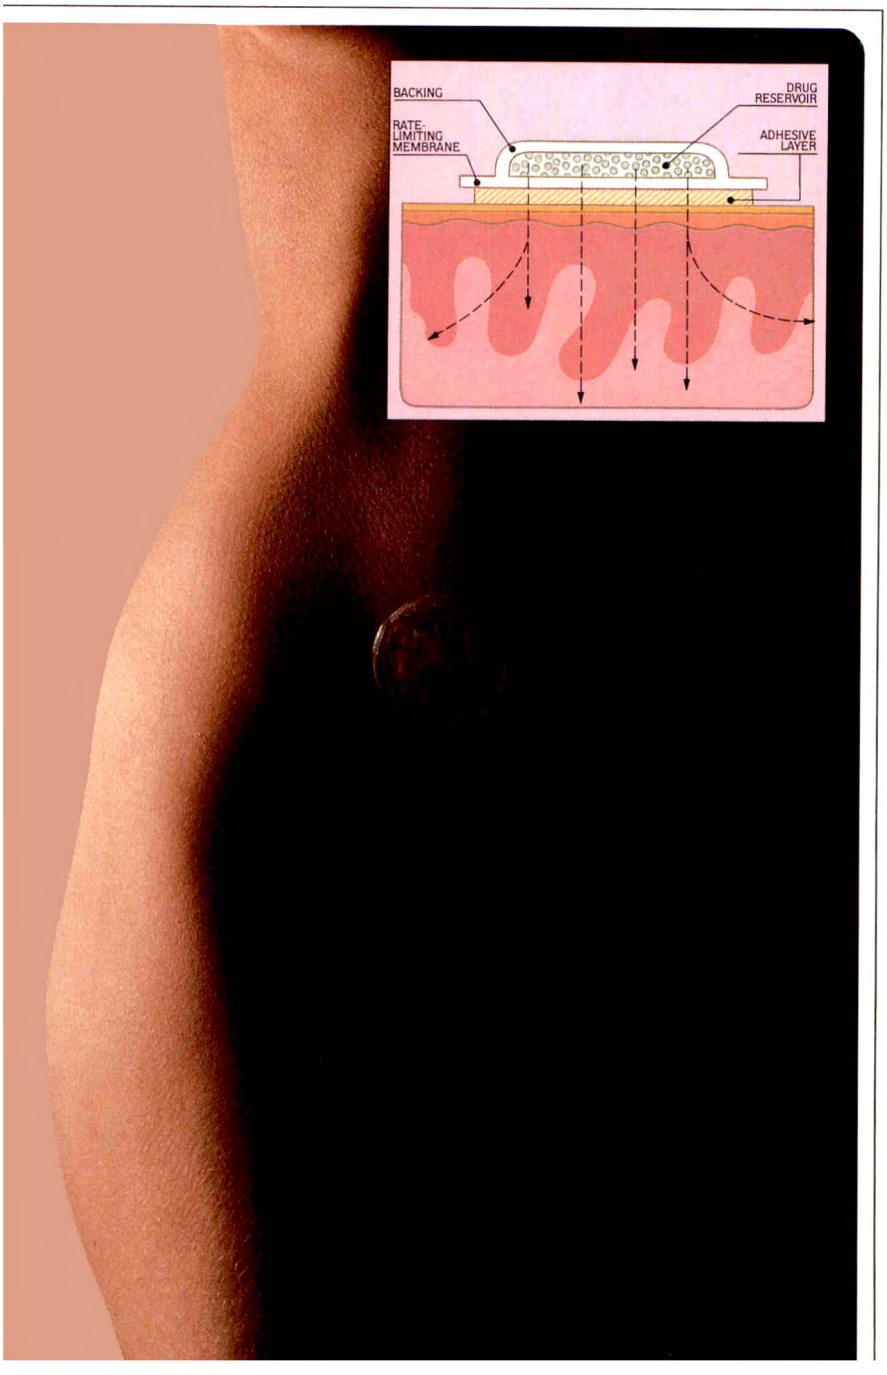
Now

The next generation of estrogen replacement therapy...



transdermal delivery

ESTRADERM®

estradiol transdermal syster

Combines the advantages of transdermal delivery...

A specially designed transdermal delivery system

Providing the natural ovarian estroge (17-beta estradiol) directly to the bloodstream and target organs; with no first-pass liver metabolism, permi use of extremely low dosage

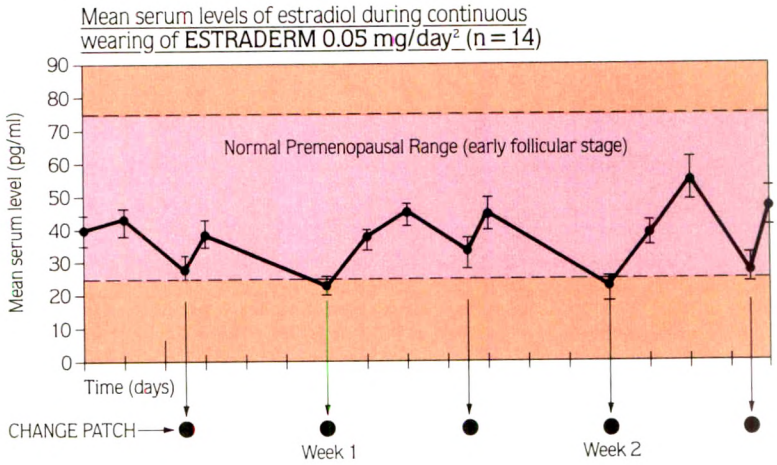
Effectively controls estrogen deficiency symptoms

Steady-state relief of hot flashes, oth menopausal symptoms associated wi hot flashes, and vaginal discomfort

Well tolerated

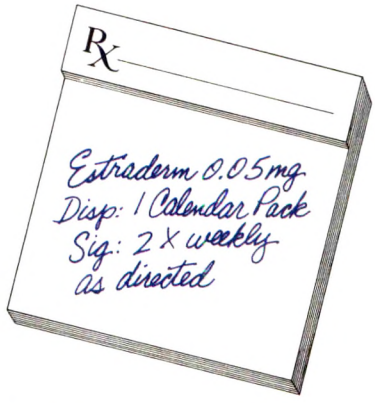
Very low incidence of systemic side effects...few local problems of consequence

Easy to use; transdermal delivery preferred 3:1 by patients over tablets[1]



Usual starting dose: a 0.05-mg syste changed twice weekly

C I B A



th the benefits of trogen replacement

ores and maintains premenopausal idiol serum levels

es estradiol levels to near-normal premenopausal ranges
ves a physiologic 1:1 ratio of estradiol to estrone

ESTRADERM®

estradiol transdermal system

Continuous delivery for twice-weekly application.
BRIEF SUMMARY OF PRESCRIBING INFORMATION.
PLEASE SEE FULL PRESCRIBING INFORMATION.

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than 1 year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer-reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5-13.9 times greater than in nonusers. The risk appears to depend both on duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that women who had been exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than four per 1000 exposures. Furthermore, a high percentage of such exposed women (30-90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data on the use of other estrogens are not available, it cannot be presumed they would not induce similar changes.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case control study estimated a 4.7-fold increased risk of limb-reduction defects in infants who had been exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses.

If Estraderm is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and of the advisability of continuation of the pregnancy.

INDICATIONS AND USAGE

Estraderm is indicated for the treatment of the following: moderate-to-severe vasomotor symptoms associated with menopause; female hypogonadism; female castration; primary ovarian failure; and atrophic conditions caused by deficient endogenous estrogen production, such as atrophic vaginitis and kraurosis vulvae.

Studies of the addition of a progestin for seven or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of endometrium suggest that 12 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks that may be associated with the inclusion of progestin in estrogen replacement regimens. The potential risks include adverse effects on carbohydrate and lipid metabolism. The choice of progestin and dosage may be important in minimizing these adverse effects.

CONTRAINDICATIONS

Estrogens should not be used in women or men with any of the following conditions:

1. known or suspected cancer of the breast;
2. known or suspected estrogen-dependent neoplasia;
3. known or suspected pregnancy (see Boxed Warning);
4. undiagnosed abnormal genital bleeding;
5. active thrombophlebitis or thromboembolic disorders;
6. history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. Induction of Malignant Neoplasms. Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.)

At the present time, there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of breast cancer, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data, there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms.

2. Gallbladder Disease. A recent study has reported a two- to threefold increase in the risk of surgically confirmed gallbladder disease in postmenopausal women receiving oral estrogens, similar to the twofold increase previously noted in users of oral contraceptives.

3. Effects Similar to Those Caused by Estrogen-Progestogen Oral Contraceptives. There are several serious adverse effects of oral contraceptives and other high-dose oral estrogen treatments, most of which have not, up to now, been documented as consequences of postmenopausal estrogen replacement therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women.

a. Thromboembolic Disease. It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least four weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. Hepatic Adenoma. Benign hepatic adenomas have been associated with the use of oral contraceptives. Although benign and rare, these tumors may rupture and cause death from intra-abdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations, but they should be considered if abdominal pain and tenderness, abdominal mass, or hypovolemic shock occurs in patients receiving estrogen. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The causal relationship of this malignancy to these drugs is not known.

c. Elevated Blood Pressure. Women using oral contraceptives sometimes experience increased blood pressure which, in most cases, returns to normal upon discontinuing the drug. There is now a report that this may occur with use of oral estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used. Ethinyl estradiol and conjugated estrogens have been shown to increase renin substrate. In contrast to these oral estrogens, transdermally administered estradiol does not affect renin substrate.

d. Glucose Tolerance. A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. Hypercalcemia. Administration of high doses of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If hypercalcemia occurs, use of the drug should be stopped and appropriate measures should be taken to reduce the serum calcium level.

PRECAUTIONS

General

1. A complete medical and family history should be taken before initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, as well as a cervical Papanicolaou test. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Because estrogens may cause some degree of fluid retention, careful observation is required when conditions that might be influenced by this factor are present (e.g., asthma, epilepsy, migraine, and cardiac or renal dysfunction).
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as uterine bleeding, mastodynia, etc.
4. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Estrogens should be used with caution in patients who have or have had endometriosis.
5. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
6. Preexisting uterine leiomyomata may increase in size during prolonged estrogen use. If this occurs, estrogen therapy should be discontinued while the cause is investigated.
7. In patients with a history of jaundice during pregnancy, there is an increased risk that jaundice will recur with the use of estrogen-containing oral contraceptives. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients.
9. Because the prolonged use of estrogens influences the metabolism of calcium and phosphorus, estrogens should be used with caution in patients with metabolic bone diseases associated with hypercalcemia and in patients with renal insufficiency.

Drug/Laboratory Test Interactions

The results of certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following changes have been observed with large doses of oral estrogen:

1. increased sulfobromophthalein retention;
2. increased prothrombin time; increased factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability;
3. increased thyroxine-binding globulin (TBG), leading to increased circulating total thyroid hormone (T_4) as measured by column or radioimmunoassay; free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered; TBG was not affected in clinical trials of Estraderm;
4. reduced response to the metyrapone test;
5. reduced serum folate concentration;
6. increased serum triglyceride and phospholipid concentration, and decreased pregnanediol excretion.

The pathologist should be informed that the patient is receiving estrogen therapy when relevant specimens are submitted.

Carcinogenesis, Mutagenesis, Impairment of Fertility

See **WARNINGS** and Boxed Warning.

Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

Pregnancy Category X

See **CONTRAINDICATIONS** and Boxed Warning.

Estrogens should not be used during pregnancy.

Nursing Mothers

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS

See **WARNINGS** and Boxed Warning regarding potential adverse effects on the fetus, induction of malignant neoplasms, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.

The most commonly reported adverse reaction to Estraderm in clinical trials was redness and irritation at the application site. This occurred in about 17% of the women treated and caused approximately 2% to discontinue therapy. Reports of rash have been rare.

The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives:

Genitourinary System: Breakthrough bleeding, spotting, change in menstrual flow; increase in size of uterine fibromyomata; change in cervical erosion and amount of cervical secretion.

Endocrine: Breast tenderness, breast enlargement.

Gastrointestinal: Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice have been observed with oral estrogen therapy.

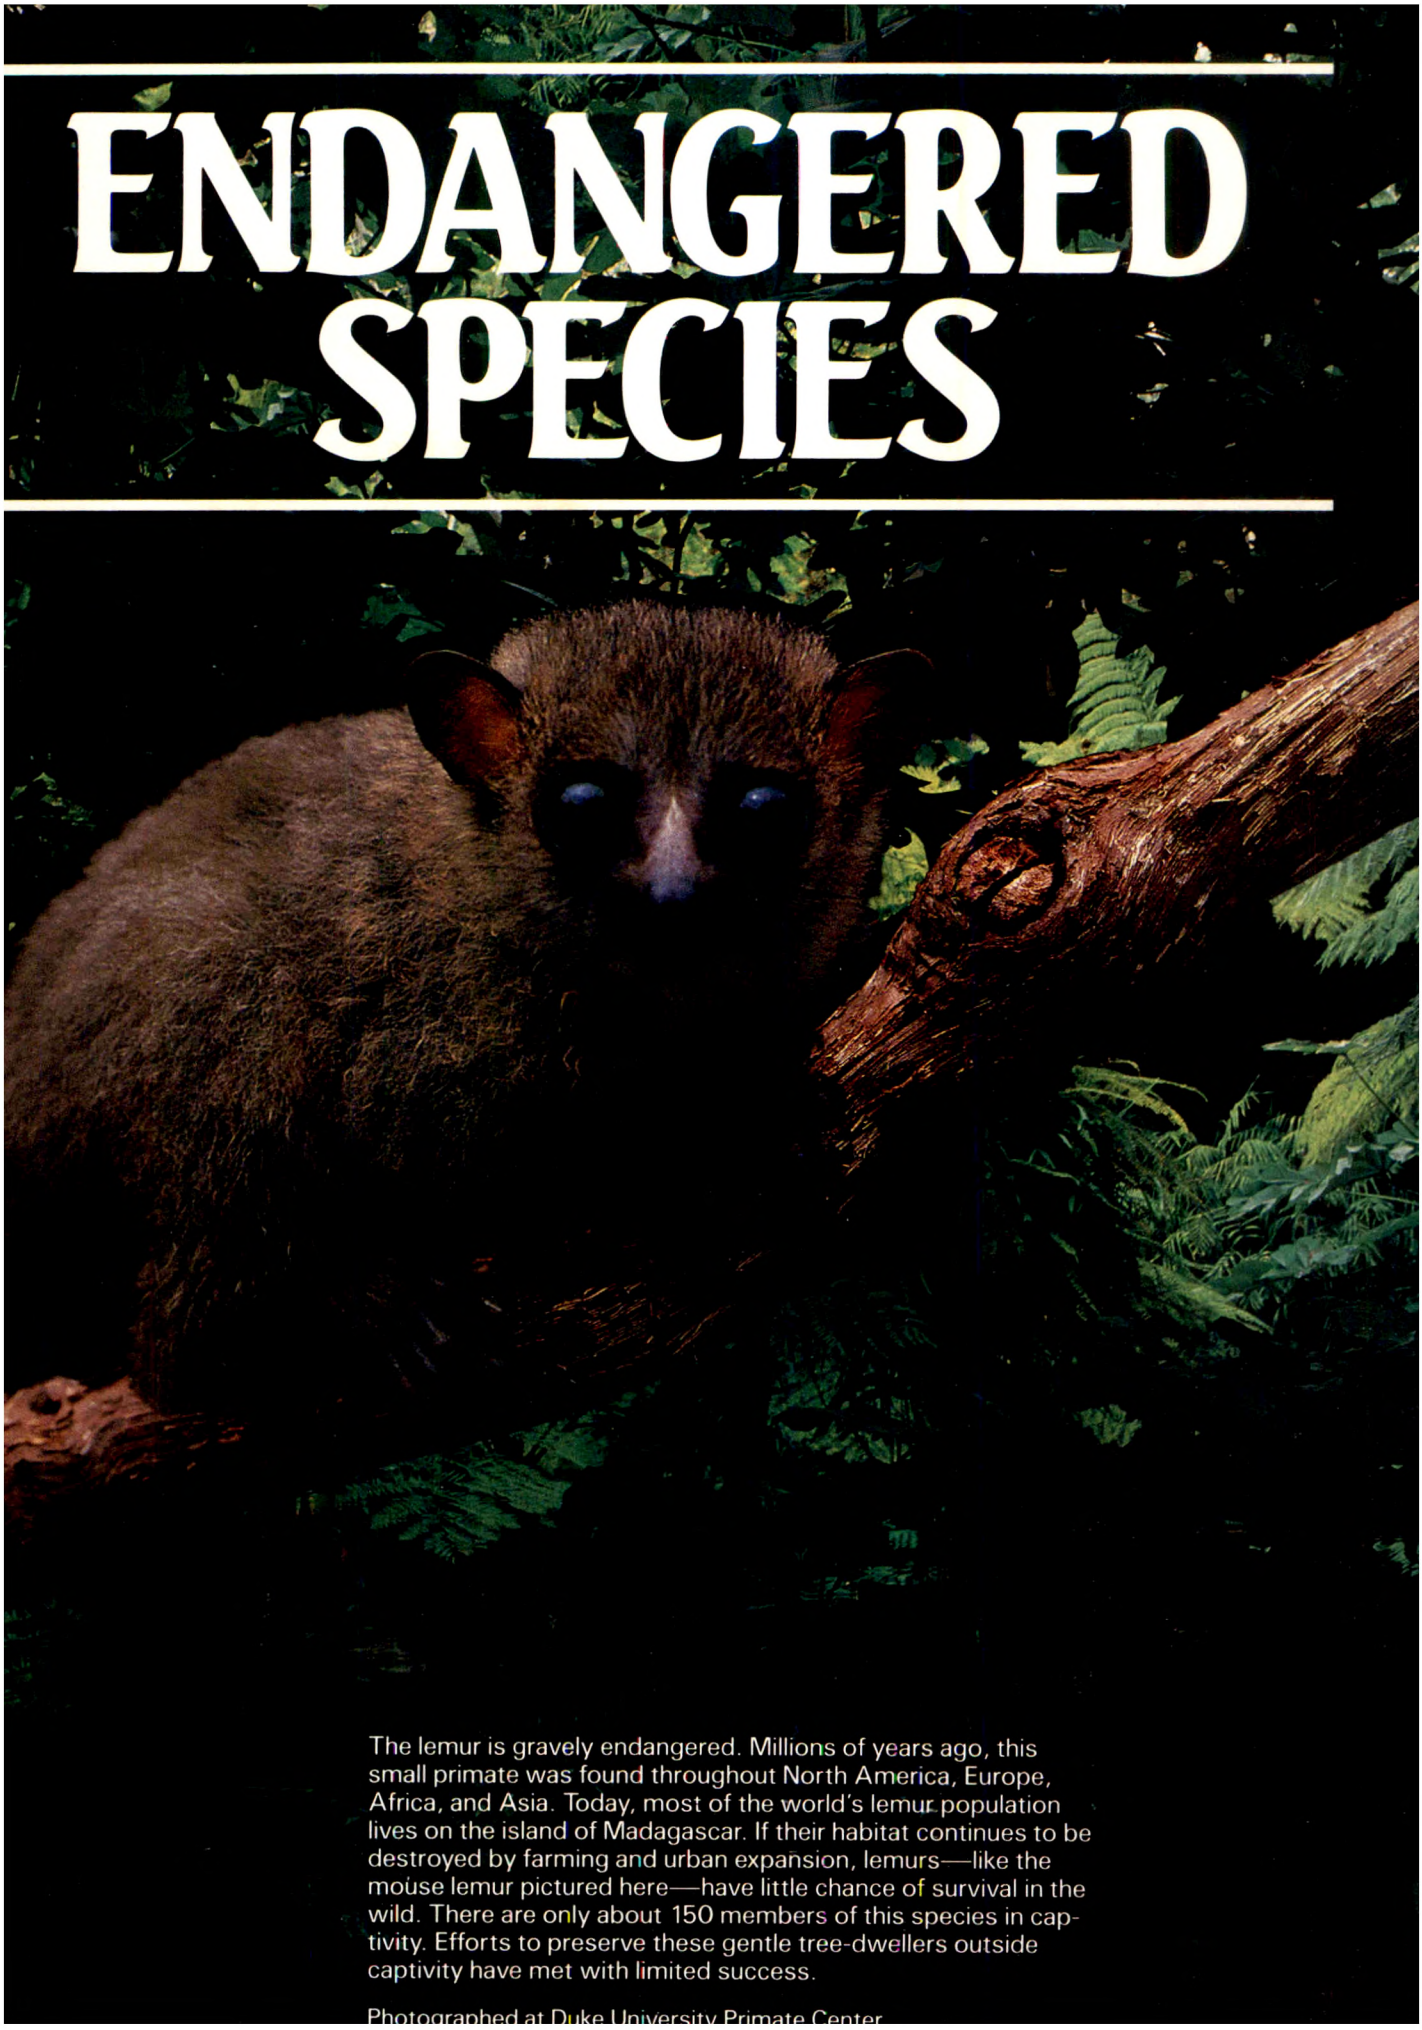
Eyes: Steepening of corneal curvature; intolerance to contact lenses.

Central Nervous System: Headache, migraine, dizziness.

Miscellaneous: Change in weight, edema, change in libido.

Do not store above 86°F (30°C).

Do not store unpouched. Apply immediately upon removal from the protective pouch.



CAUTION: Federal law prohibits dispensing without prescription.

ENDANGERED SPECIES

The lemur is gravely endangered. Millions of years ago, this small primate was found throughout North America, Europe, Africa, and Asia. Today, most of the world's lemur population lives on the island of Madagascar. If their habitat continues to be destroyed by farming and urban expansion, lemurs—like the mouse lemur pictured here—have little chance of survival in the wild. There are only about 150 members of this species in captivity. Efforts to preserve these gentle tree-dwellers outside captivity have met with limited success.

Photographed at Duke University Primate Center

ENDANGERED SPECIES?

Is the practice of obstetrics endangered? Its survival is threatened by factors that have the potential to diminish significantly the number of practicing obstetricians. The continuing increase in the number of malpractice lawsuits against physicians and the corresponding inflation of liability insurance premiums have plunged the obstetrics specialty into a crisis.

Patient-initiated litigation is now so common that 1 in 6 obstetrician/gynecologists is sued each year, compared with 1 in 20 only ten years ago. As a result, obstetricians pay three to four times more for malpractice insurance than do physicians in most other specialties.

Survival of the practice of obstetrics is further jeopardized because fewer students are entering the specialty and the number of experienced physicians leaving obstetrics or retiring early is on the rise. For many physicians, the crisis has taken the joy out of practicing medicine.

AVOIDING THE DANGER OF EXTINCTION

Immediate action is necessary in order to preserve the practice of obstetrics. In response to this need, G.D. Searle & Co. has organized the Searle Alliance for Health Care. Its purpose is to help lead a national effort to resolve the medical professional liability crisis.

Components of a campaign developed by the Alliance include: nationwide teleconferences and audioconferences; strategy to petition legislators for reform; educational programs and seminars; and national advertising to raise public consciousness of the crisis.

Operating on a national and personal level, the Searle Alliance for Health Care can provide information to help you in your practice. Learn more about medical professional liability and how we can provide information about the problem of professional liability. Contact your Searle representative for more information on the Searle Alliance for Health Care.

Demulen 1/35™
(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™

(ethynodiol diacetate 1 mg, ethinyl estradiol 35 mcg)

Demulen 1/35™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 35 mcg. Each blue tablet in Demulen 1/35-28 is a placebo containing inert ingredients.

Demulen 1/50™ Each white tablet contains ethynodiol diacetate 1 mg and ethinyl estradiol 50 mcg. Each pink tablet in Demulen 1/50-28 is a placebo containing inert ingredients. **Indication and usage:** For prevention of pregnancy. Pregnancy rate for products with ≥35 mcg ethinyl estradiol or ≥50 mcg mestranol is ≤1/100 woman-years. With ≤35 mcg ethinyl estradiol, rate is slightly higher; with progestogen-only oral contraceptives (OCs), rate is about 3. Precise comparisons cannot be made. Rates for other methods have been published. *Dose-related Thromboembolic Risk:* Studies showed positive association between OC estrogen dose and thromboembolic risk. It is in keeping with good therapeutics to minimize estrogen exposure. Prescribe product containing least amount of estrogen compatible with acceptable pregnancy rate and patient acceptance. Start new users on ≤50 mcg estrogen. **Contraindications:** Thrombophlebitis, thromboembolic disorders, past history of deep vein thrombophlebitis or thromboembolic disorders; cerebrovascular disease, myocardial infarction or coronary artery disease, or past history of these; known or suspected breast carcinoma, estrogen-dependent neoplasia, or pregnancy; undiagnosed abnormal genital bleeding; past or present, benign or malignant liver tumors developing during use of estrogenic products. **Warnings:**

Cigarette-smoking increases risk of serious cardiovascular side effects from OC use. Risk increases with age and heavy smoking (15 or more cigarettes/day) and is quite marked in women over 35. OC users should be strongly advised not to smoke. OCs are associated with increased risk of several serious conditions including venous and arterial thromboembolism, thrombotic and hemorrhagic stroke, myocardial infarction, visual disorders, hepatic tumors, gallbladder disease, hypertension, fetal abnormalities. Practitioners should be familiar with the available information relating to these and other risks.

1. *Thromboembolic disorders and other vascular problems:* Increased risk of thromboembolic and thrombotic disease associated with OCs is well established. A British study showed increased risk for fatal venous thromboembolism (TE). British and U.S. studies showed increased risk for nonfatal disease. U.S. studies showed increased risk for stroke. OC users were 2-11 times more likely to manifest these diseases without evident cause. In a study of idiopathic deep vein thrombosis and pulmonary embolism (PE), projected hospitalization rates for ages 16-40 were 47/year/100,000 users and 5 for nonusers. Overall excess mortality from PE or stroke was 1.3-3.4 deaths/year/100,000 users and increased with age. *Cerebrovascular Disorders:* In a study of stroke with and without predispositions, risk of hemorrhagic stroke was 2 times greater and thrombotic stroke 4.0-9.5 times greater in users. Mortality trends in 21 countries indicate that changes in cardiovascular mortality were associated with changes in OC prevalence. The Royal College of GPs (RCGP) reported on its prospective study: "A statistically significant higher rate of reporting of cerebrovascular accidents in Takers is evident, but the numbers are too small to justify an estimation of the degree of risk." A 1981 analysis showed a 4-fold increased mortality in users from circulatory diseases, mainly myocardial infarction (MI) and hemorrhagic stroke. Excess mortality was associated with age and smoking. A 1983 analysis showed elevated cerebrovascular disease, increasing with use to 8 yrs, including cerebral thrombosis or embolism and TIA. Peripheral arterial disease and MI were increased. Women over 30 had more arterial disease, being greatest in smokers. Arterial case-fatality was 2-3 times greater for users who smoked. Family Planning Assoc. (FPA) found significant association between OC use and stroke; increased risk for venous thrombosis and PE was 4-fold and statistically significant. Mortality from nonrheumatic heart disease was greater in ever-users. In the Walnut Creek Study, subarachnoid hemorrhage risk was associated with smoking, age, and OC use. *Myocardial Infarction:* Increased risk of MI associated with OCs was reported in Britain, as previously suspected. The morbidity study found the greater the number of risk factors for coronary artery disease (smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk, regardless of OC use. OCs were an additional risk factor. Excess rate of fatal MI was 3.5/year/100,000 users aged 30-39 and 20 for ages 40-44. (These are based on British statistics with acute MI death rates 2-3 times less than the U.S. Similar estimates for the U.S. are 25.7 for users aged 30-39 with predispositions vs 1.5 without; for ages 40-44, 86.2 vs 5.1.) Excess hospitalization rate for nonfatal MI in Britain was 3.5/year/100,000 users aged 30-39 and 47 for ages 40-44. Smoking major predisposing condition to MI. In terms of relative risk, nonsmoking OC users are twice as likely to have fatal MI as nonsmoking nonusers. Smoking users have a 5-fold greater risk than nonsmoking users, but a 10-12-fold greater risk than nonsmoking nonusers. Amount of smoking is an important factor. In determining importance of these risks, give serious consideration to rates in table below. Importance of other predispositions cited above in determining relative and absolute risks has not been quantified; it is likely the same synergism exists, but perhaps to a lesser extent. U.S. studies similarly relate MI, OCs, smoking, and age.

Estimated Mortality Rate from Myocardial Infarction per 100,000 Women/Year

	Aged 30-39:	*Users*	*Nonusers*	*Aged 40-44:*	*Users*	*Nonusers*
All smokers		10.2	2.6		62.0	15.9
≥15 cigarettes daily		13.0	5.1		78.7	31.3
<15 cigarettes daily		4.7	0.9		28.6	5.7
Nonsmokers		1.8	1.2		10.7	7.4
Smokers and nonsmokers		5.4	1.9		32.8	11.7

Risk of Dose: Reports of TE after use of OCs with ≥50 mcg estrogen received by drug safety committees in Britain, Sweden, and Denmark were compared with distribution expected from market research sales estimates. A positive correlation was found between estrogen dose and reporting of TE, including coronary thrombosis, in excess of that predicted by sales. OCs with ≥100 mcg estrogen were associated with higher TE risk than those with 50-80 mcg. Estrogen quantity may not be the sole factor; influence of progestogens was not considered, which may be responsible for certain discrepancies in the data. No significant differences were noted between OCs containing same estrogen dose nor between ethinyl estradiol and mestranol. In Britain certain TE conditions were associated with progestogen or estrogen dose. In Sweden reports of TE decreased when higher estrogen doses were no longer prescribed. Studies on TE risk with progestogen-only OCs have not been done. Cases have been reported for these; they are not presumed free of risk. In a U.S. case-controlled study, relative risk of OC use 1 month before hospitalization for various types of TE was calculated. If relative estrogenic potency and possible influence of different progestogens are ignored, OCs may be divided into those with <100 mcg and those with ≥100 mcg estrogen. For all cases combined, larger doses were associated with only slightly higher risk; for idiopathic cases risk was doubled with larger doses, but confidence limits overlapped and differences were not significant. Apparently there was less increased risk for cases with predispositions. In FPA study no nonhemorrhagic strokes occurred with <50 mcg estrogen, vs 13 with higher doses. TE risk in users and nonusers increases with age. OCs have been considered an independent risk factor. *Persistence of Risk* after OC discontinuation was reported for circulatory disease, nonrheumatic heart disease, and cerebrovascular disease, including subarachnoid hemorrhage, cerebral thrombosis, and TIA. *Excess Mortality from Circulatory Diseases:* A U.K. prospective study estimated annual mortality from circulatory diseases for OC users and nonusers by age, smoking, and duration of use. Excess mortality was 23/100,000 users (2 and 10 for ages 25-34, 15 and 48 for ages 35-44, 41 and 179 for ages >44, for nonsmokers and smokers, respectively). Risk was significant only for smokers over 34. Most deaths were due to subarachnoid hemorrhage or ischemic heart disease. Risk for ever-users rose with parity. One study estimated risk of death with various contraceptive methods, each estimate including risk of method (eg, TE for OCs) plus risk due to pregnancy or abortion in cases of method failure. This latter risk varies with effectiveness. It concluded mortality with all methods is low and below that of childbirth, except for OC users over 40 who smoke. Heavy smokers have double the risk of smokers, light smokers about half. Mortality with OC use in nonsmokers over 40 is higher than with any other method in that age group. Lowest mortality is with condom or diaphragm backed up by early abortion. Risk of TE and thrombotic disease with OCs increases with age after 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia, and especially cigarette smoking. Based on current data, the chart gives gross estimates of risk of death from circulatory disorders associated with OCs:

Risk is: A—very high; B—high; C—moderate; D—low.	Age: <30	30-39	≥40
Heavy smokers (≥15/day)	C	B	A
Light smokers (<15/day)	D	C	B
Nonsmokers, no predispositions	D	C,D	C
Nonsmokers, with predispositions	C	C,B	B,A

Be alert to earliest manifestations of TE and thrombotic disorders (eg, thrombophlebitis, PE, cerebrovascular insufficiency, coronary artery disease, MI, retinal thrombosis, mesenteric thrombosis). Should any be suspected, discontinue OCs immediately. A 4-7-fold increased risk of postsurgery TE was reported in users; if feasible discontinue OCs at least 4 weeks before surgery or in prolonged immobilization. Before resuming OCs, weigh risks of postsurgery TE complications against contraceptive needs. The RCGP prospective study reported higher incidence of superficial and deep vein thrombosis in users, the former correlated with progestogen dose. The data suggest varicose veins have little effect on development of deep vein thrombosis but substantially increase risk of superficial vein thrombosis, risk depending on severity of varicosities. **2.** *Ocular lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OCs. Discontinue if there is unexplained, gradual or sudden, partial or complete loss of vision; proptosis or diplopia; papilledema; or evidence of retinal vascular lesions. Institute diagnostic and therapeutic measures. **3.** *Carcinoma:* Long-term estrogen in certain animals increases carcinomas and/or nonmalignant neoplasms, such as those of breast, uterus, cervix, vagina, ovary, liver, pituitary. Some synthetic progestogens, none currently in OCs, increase incidence of benign and malignant mammary nodules in dogs. There is evidence that estrogens increase risk of human endometrial carcinoma. In case-controlled studies, increased risk (2.2-13.9 times) associated endometrial carcinoma with prolonged estrogen for menopausal symptoms. Risk was independent of other known risk factors and depended on duration of use and dose. This is supported by increased endometrial cancer incidence since 1969 in areas with cancer-reporting systems, which may be related to rapidly expanding estrogen use. There is no evidence that natural estrogens are more or less hazardous than synthetics at equi-estrogenic doses. Of the first 30 cases of endometrial carcinoma in OC users under 40, those without predispositions (eg, irregular bleeding before OCs, polycystic ovaries) occur nearly always with no-longer-marketed sequential OCs. No statistical association is reported suggesting increased endometrial cancer v combination or progestogen-only OCs, though individual cases were reported. Studies show no increased breast cancer with OCs or estroge However, greater risk was noted in OC users with benign breast disease or long-term (2-4 years) use. One study found greater risk of bre cancer with >4 years OC use prior to first full-term pregnancy. Risk of breast cancer with menopausal estrogens rose and further increa with duration of follow-up. OCs or estrogen were related to breast cancer in connection with other risk factors. Decrease in benign bre tumors in OC users is well known. Some studies suggested increased risk of cervical dysplasia, erosion, and carcinoma in long-term usi Cervical microglandular hyperplasia has been reported. In summary, there is no consistent evidence from human studies of increased car risk with OCs. Close surveillance is, however, essential. In undiagnosed persistent or recurrent abnormal vaginal bleeding, consi nonfunctional causes and take diagnostic measures to rule out malignancy. Carefully monitor users with strong family history of breast car or with breast nodules, fibrocystic disease, recurrent cystic mastitis, abnormal mammograms, or cervical dysplasia. **4.** *Hepatic adenomas,* have been associated with OCs. In 1 study OC formulations with high "hormonal potency" were associated with higher risk, as was age o 30. Though benign, these lesions may rupture and cause fatal hemoperitoneum in short- or long-term users. Two studies related risk duration of use, being much greater after ≥4 years. Long-term OC users have an estimated adenoma incidence of 3-4/year/100,0 Consider such lesions in users with abdominal pain, tenderness, mass, or shock. About 25% present with abdominal masses, up to half w acute hemoperitoneum. Radiologic and lab studies may not be helpful; liver scans may show local defect. Hepatic arteriography or CAT n be useful. Hepatocellular carcinoma risk is increased 7-20 times in users for 8 or more years. OCs are contraindicated in case of past present, benign or malignant liver tumors developing during use of estrogenic products. **5.** *Use in or immediately preceding pregnancy, b defects, malignancy in offspring:* Estrogens or progestogens during early pregnancy may seriously damage offspring. Females exposed in ut to DES and other nonsteroidal estrogens may have increased risk of vaginal or cervical cancer. Though OCs may not enhance this risk, moni such patients carefully. From 30-90% of DES-exposed women develop benign vaginal or cervical adenosis, which could be premalignant. Di exposed daughters have more unfavorable pregnancy outcomes. Males so exposed may develop urogenital and sperm defects. Other estrogi may mimic DES. Reports relate fetal exposure to female sex hormones and congenital anomalies, eg, VACTERL for vertebral, anal, cardi tracheoesophageal, renal, and limb defects. There appears preferential expression by males. There was a 4.7-fold increased risk of lir reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal pregnancy tests, or treatment for threater abortion). Some exposures were very short, being only a few days. Cardiovascular defects in children exposed to female hormones, includ OCs, during early pregnancy occurred in 18.2/1,000 births, compared to 7.8 for those unexposed (P<.05). More twinning was reported conceptions shortly after OC discontinuance. Female sex hormones were used for threatened or habitual abortion, but there is considera evidence estrogens are ineffective and no evidence progestogens are effective. Triploidy and possibly other polyploidy may be increased abortuses from women becoming pregnant soon post-OC. These almost always abort spontaneously. It is unknown if spontaneous abortion increased soon after stopping OCs. Increased chromosome aberrations have been reported. Safety of OCs in pregnancy has not be demonstrated. Rule out pregnancy in using OCs and always consider it if withdrawal bleeding does not occur. If 2 consecutive periods a missed rule out pregnancy before continuing. If user deviates from regimen, consider pregnancy at first missed period and withhold OCs. pregnancy is confirmed, apprise patient of potential fetal risks and discuss continuation of pregnancy. Users discontinuing for pregnancy sho use alternative contraception for 3 months before attempting to conceive, though this is not based on precise information. Do not u progestogen-only or progestogen-estrogen drugs as pregnancy tests. **6.** *Gallbladder disease* risk, surgically confirmed, appeared after 2 yea use and doubled after 4-5 years in 1 study; it appeared in 6-12 months' use in another. **7.** *Carbohydrate and lipid metabolism:* Decreas glucose tolerance occurs in a significant number of users; carefully observe diabetic and prediabetic patients. Triglycerides and to phospholipids may increase. **8.** *Elevated blood pressure* (BP) occurs in some users in a few months, and degree may relate to progestog dose. Hypertension prevalence in users is not higher in the first year, but increases with longer exposure; in the 5th year it is 2½—3 tim the first year. Age is strongly correlated with hypertension in users. Those with history of elevated BP (hypertension), preexisting ren disease, history of toxemia or elevated BP in pregnancy, familial tendency to hypertension or its consequences, or history of excessive weig gain or fluid retention during menstrual cycles may be more likely to develop elevated BP on OCs and should be monitored closely. Ev though elevated BP may be in "normal" range, do not ignore implications. Follow closely, particularly those with other risk factors cardiovascular disease or stroke. High BP may or may not persist after stopping OCs. **9.** *Headache:* Onset or exacerbation of migraine development of headache of a new pattern that is recurrent, persistent, or severe requires stopping OCs and evaluating cause. **10.** *Bleedi irregularities:* Breakthrough bleeding (BTB), spotting, and amenorrhea are frequent reasons for discontinuing. In BTB, as in all cases of irregu bleeding, consider nonfunctional causes. In undiagnosed persistent or recurrent bleeding, rule out pregnancy or malignancy. If pathology excluded, time or change to another product may suffice. Change to a higher-estrogen OC only when necessary as this may increa thromboembolic risk. Those with history of oligomenorrhea or secondary amenorrhea or without established regular cycles may be anovulatc or amenorrheic after discontinuing. Those with such problems should be so informed and other methods encouraged. Post-use anovulatic possibly prolonged, may occur in women without previous irregularities. Higher incidence of galactorrhea and of pituitary tumors has be associated with postpill amenorrhea. One stucy reported 16-fold increased prevalence of pituitary prolactin-secreting tumors in patients wi postpill amenorrhea when galactorrhea was present. **11.** *Ectopics:* In failures with combination OCs, the ratio of ectopic to intrauteri pregnancies is no higher than in nonusers. There may be increased risk of ectopics after discontinuing. **12.** *Breast feeding:* OCs may decrea quantity and quality of milk. A small fraction of OC steroids appears in milk. Effects if any on child are unknown. If feasible defer OCs un after weaning. **13.** *Infertility* may occur after discontinuing OCs. While impairment diminishes with time, there is still an appreciable differen in nulliparas aged 25-29 after 30 months; difference is negligible after 48 months. In nullips aged 30-34 impairment persists to 72 month and is more severe for 2-year users. In paras aged 25-34, difference is negligible after 30 months. **Precautions:** Conduct complete histo and physical prior to OC use and annually thereafter. Include breasts, abdomen, and pelvis, with BP, Pap, and lab tests. Preexisting uterir leiomyomata may enlarge. Mental depression may occur; with positive history, observe carefully and discontinue if serious recurrence. Flu retention may occur; prescribe cautiously and monitor carefully in convulsive disorders, migraine, asthma, or cardiac, hepatic, or ren dysfunction. History of jaundice in pregnancy increases risk of recurrence on OCs; observe carefully and discontinue if it occurs. Cholestat jaundice occurred after OC and troleandomycin use. OC/cyclosporine combination may be hepatotoxic. Steroids may be poorly metabolized liver dysfunction and should be given cautiously. Tryptophan metabolism may be disturbed and result in pyridoxine deficiency; megaloblast anemia has been reported. Serum folate may be depressed and may be exacerbated in post-OC pregnancy. Advise pathologist of OC use whe submitting specimens. Endocrine and liver function tests may be altered; repeat abnormal tests after stopping for 2 months. These have bee observed: increased BSP retention and other abnormalities in liver function tests; increased prothrombin and coagulation factors VII, VIII, D X; decreased antithrombin III, increased platelet aggregability; increased thyroid-binding globulin leading to increased circulating total thyroi hormone (PBI, T^4); decreased T^3 uptake, unaltered free T^4, decreased pregnanediol excretion; reduced metyrapone response; increased bloc transcortin, corticosteroid, triglyceride, phospholipid, reduced serum folate; impaired glucose tolerance; altered plasma trace minerals. Influenc of prolonged OC use on pituitary, ovarian, adrenal, hepatic, or uterine function, or on immune response not established. OCs may mask onsi of climacteric. Cervical chlamydial prevalence is increased; do not assume OC protects against chlamydial PID. *Information for patients.* Se patient labeling. *Drug interactions.* OC effectiveness may be decreased and more BTB occur with rifampin, isoniazid, ampicillin, neomycir penicillin V, tetracycline, chloramphenicol, sulfonamides, nitrofurantoin, griseofulvin, barbiturates, phenytoin, carbamazepine, primidon phenylbutazone, analgesics, tranquilizers, antimigraines. OCs may alter effectiveness of oral anticoagulants, anticonvulsants, tranquilizer tricyclic antidepressants, antihypertensives, theophylline, caffeine, vitamins, hypoglycemics, clofibrate, glucocorticoids, acetaminophen **Adverse reactions:** Increased risk of the following serious adverse reactions has been associated with OCs: thrombophlebitis an thrombosis; pulmonary embolism; arterial thromboembolism; Raynaud's disease, myocardial infarction; coronary thrombosis; cerebral thrombo sis; cerebral hemorrhage; hypertension; gallbladder disease; Budd-Chiari syndrome; benign adenomas and other hepatic lesions, with or without intra-abdominal bleeding, liver cancer, congenital abnormalities. There is evidence of association between the following and OCs, though confirmatory studies have not been done: mesenteric thrombosis; neuro-ocular lesions, eg, retinal thrombosis and optic neuritis. The followin are believed drug related: nausea, vomiting, gastrointestinal symptoms, BTB, spotting, change in menstrual flow, dysmenorrhea, amenorrhe during and after use, infertility post-OC, edema, chloasma or melasma, which may persist post-OC, breast changes (tenderness, enlargemen secretion), weight changes, change in cervical erosion and secretion, endocervical hyperplasia, lactation decrease, cholestatic jaundice migraine, enlarged uterine leiomyomata, allergic rash, mental depression, reduced carbohydrate tolerance, vaginal candidiasis, change i corneal curvature (steepening), intolerance to contact lenses. Association not confirmed or refuted for: premenstrual-like syndrome, cataracts libido changes, chorea, appetite changes, cystitis-like syndrome, headache, paresthesia, nervousness, dizziness, auditory disturbances, rhinitis fatigue, backache, hirsutism, scalp hair loss, erythema multiforme or nodosum, hemorrhagic eruption, herpes gestationis, hemolytic uremia malignant hypertension, itching, vaginitis, porphyria, impaired renal function, acute renal failure, sometimes irreversible, PVCs, abnormal EKG pulmonary hypertension, TTP, anemia, pancreatitis, hepatitis, colitis, Crohn's disease, gingivitis, dry socket, lupus erythematosus, rheumatoi arthritis, pituitary tumors (eg, adenoma) with amenorrhea and/or galactorrhea after use, malignant melanoma, endometrial, cervical, and breas carcinoma. **Acute overdosage:** Serious ill effects have not been reported after large acute doses of OCs in young children. Nausea an withdrawal bleeding might occur. **Important note: Complete prescribing information should be consulted prior to use an is available on request.**

Management of the diethylstilbestrol-exposed pregnant patient: A prospective study

Jack Ludmir, M.D., Mark B. Landon, M.D., Steven G. Gabbe, M.D., Philip Samuels, M.D., and Michael T. Mennuti, M.D.

Philadelphia, Pennsylvania

Over a 5-year period we have managed 63 diethylstilbestrol-exposed pregnant patients with a standardized protocol requiring weekly cervical examination and decreased physical activity of the patient. Twenty-six patients (42%) underwent a prophylactic cerclage for a history of second-trimester loss or a hypoplastic cervix on initial clinical examination (group I). Thirty-six patients (58%) were followed expectantly (group II). Sixteen patients (44%) in group II demonstrated cervical change and required an emergency cerclage. Twenty-one patients were managed expectantly with no cerclage. The gestational age at delivery for group I was 37.7 ± 2.80 versus 34.5 ± 6.9 weeks for patients without a cerclage ($p = 0.04$). There were no perinatal deaths if a cerclage was performed, whereas there were five deaths (24%) in the group without cerclage. The five deaths occurred at a mean gestational age of 24.40 ± 4.0 weeks and a mean birth weight of 614.00 ± 441.73 gm. Patients with a hypoplastic cervix or prior reproductive loss had a better outcome with early cerclage than patients with a normal cervix followed expectantly. We presently lack a reliable method to detect the diethylstilbestrol-exposed patient at greatest risk for perinatal loss. Based on our experience we believe that placement of a cerclage early in pregnancy should be a strong consideration. (Am J Obstet Gynecol 1987;157:665-9.)

Key words: Cerclage, incompetent cervix, diethylstilbestrol pregnancy

Poor reproductive outcome has been described in several studies of diethylstilbestrol-exposed women exhibiting cervicovaginal abnormalities.[1-3] Adverse pregnancy outcomes have been observed in as many as 58% of these women.[4] Increased incidences of ectopic pregnancy, prematurity, and perinatal death have contributed to pregnancy wastage in diethylstilbestrol-exposed women. Although the frequency of viable pregnancy outcomes has been found to range from 42% to 75%, only 40% to 63.5% of these patients can be expected to reach term.[2-7]

Kaufman et al.[8] have demonstrated a greater incidence of upper genital tract abnormalities in diethylstilbestrol-exposed progeny. When these authors related upper genital tract abnormalities to reproductive outcome, the patients with such abnormalities were found to have worse reproductive outcomes when compared with patients with normal uterine anatomy. These authors, however, could not relate a specific clinical pattern of pregnancy loss to the cervicouterine changes observed. The possibility that cervical incompetence is increased in the diethylstilbestrol-exposed woman was first suggested by Singer and Hochman[9] and was later supported by Goldstein.[10] Successful pregnancy outcomes for these patients with cerclage were subsequently reported.[1] Other authors have cautioned against the liberal use of cerclage in diethylstilbestrol-exposed women, reserving cerclage placement for cases in which the past obstetric history clearly indicates an incompetent cervix.[2, 6, 8]

The purpose of this study was to determine if pregnancy outcome could be improved with a standard management protocol emphasizing the aggressive use of cerclage in diethylstilbestrol-exposed pregnant women. The results of such a study could provide important information for the care of a large group of women who are currently of reproductive age.

Methods

Beginning in 1981, 63 pregnant women with a prior history of diethylstilbestrol exposure in utero received antepartum care in our institution. These women were managed according to a standard protocol of: (1) weekly or biweekly cervical examinations and (2) limited physical activity. Patients who were found on initial examination to have normal cervical length and appearance as well as those without prior pregnancy loss were followed expectantly. Early elective cerclage (12 to 14 weeks) was performed in patients with a hypoplastic cervix (less than 1 cm in length) on initial clinical

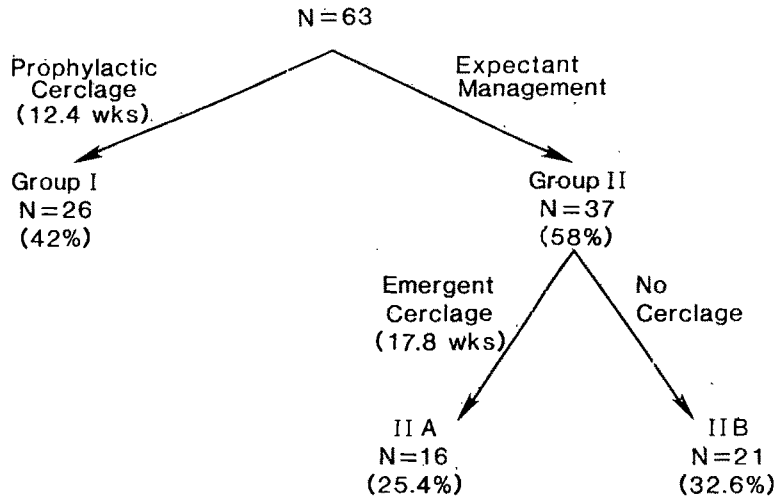

Fig. 1. Management protocol of the 63 diethylstilbestrol-exposed pregnant patients studied.

Table I. Pregnancy outcome in diethylstilbestrol-exposed women undergoing prophylactic (early) cerclage—group I

	Ia; previous loss (n = 13)	*Ib; hypoplastic cervix (n = 13)*
Birth weight (gm)*	2682.92 ± 599.07	3195.46 ± 446.15
Gestational age at delivery (wk)*	36.4 ± 3.1	38.9 ± 1.7
Gestational age at first episode of PML (wk)*	28.2 ± 1.8	27.4 ± 2.9
Days in hospital owing to PML or cervical change*	27.1 ± 19.8	19.7 ± 8.6
PROM	1	1
Perinatal deaths	0	0
Cervical lacerations	1	2

PML, preterm labor; PROM, premature rupture of the membranes.
*There were no significant differences between groups Ia and Ib by Student's *t* test.

examination and in those with a history of prior second-trimester loss. Emergent cerclage was attempted in patients demonstrating cervical effacement or dilatation that was confirmed by two examiners before 22 weeks' gestation. All patients exhibited normal cervical cytology before and during gestation. Weekly cervical examinations were performed after the cerclage was placed. Ultrasound assessment of the lower uterine segment and cervix was not routinely done.

Results

The study group of 63 women consisted of 21 primigravidas, 17 patients in their second pregnancy, and 25 with two or more previous pregnancies. The mean ages for these three groups were 29.9 28.9, and 30.8 years, respectively. Eighteen patients (28.5%) had been studied by hysterosalpingography before pregnancy; 12 of these 18 patients (66%) demonstrated a uterine abnormality. Thirteen patients (21%) were judged to have a hypoplastic cervix. Of the 21 primigravidas six (28.6%) had undergone a previous hysterosalpingography with results being abnormal in three, 24% had a hypoplastic cervix, and in 71.4% examination revealed evidence of cervicovaginal abnormalities, mainly adenosis. For the primigravidas who underwent hysterosalpingography before pregnancy, an abnormal hysterosalpingography predicted only 50% of cases in which premature cervical effacement or dilatation developed.

Of the 63 patients studied 26 (42%) underwent an elective prophylactic cerclage at a mean gestational age of 12.4 weeks (group I). This group consisted of 13 women with a hypoplastic cervix (group Ia) and 13 women with a history of second-trimester loss (group Ib). Thirty-seven patients (58%) were managed expectantly (group II). This group included 16 primigravid women. Sixteen (25.4%) group II patients, designated group IIa, subsequently required emergent cerclage for cervical change at a mean gestational age of 17.8 weeks. The remaining 21 patients, group IIb, were followed expectantly and did not undergo cerclage (Fig. 1).

Table I details pregnancy outcome in the elective cerclage group. No perinatal losses were observed in these 26 patients. The only complications encountered were three cervical lacerations repaired without incident at the time of delivery.

Results for those patients managed expectantly (group II) are presented in Table II. Although the birth weights and gestational ages achieved were lower in this group when compared with group I patients, these differences were not statistically significant. There were no perinatal losses observed in the emergent cerclage group, and in only one patient did delivery take place before 30 weeks. Table III compares the outcomes for group I versus groups IIa and IIb. The mean gestational age for the elective cerclage group (37.7 weeks) was significantly greater than that achieved when an elective cerclage was not performed (34.7 weeks, $p = 0.04$). Two patients who underwent cerclage had delivery before 30 weeks. These included a 29-week delivery (birth weight 950 gm) and a 29.5-week delivery (birth weight 1110 gm). Both infants survived. Perinatal losses were significantly higher in patients who did not undergo cerclage. In total 88% of patients who underwent an early prophylactic cerclage were delivered of their infants at term as compared to 75% of the emergency cerclage group and 70% of patients without cerclage. Overall, 54% of the patients in the study experienced preterm labor, and 25% received intravenous tocolytic therapy.

The five perinatal deaths in patients who did not have a cerclage occurred at a mean gestational age of 24.4 ± 4.0 weeks. These infants had a mean birth weight of 614.00 ± 441.73 gm. All of these patients experienced premature rupture of membranes anywhere from 3 to 7 days after a normal cervical examination. Four neonatal deaths were caused by prematurity, and one was due to sepsis. Three of these five patients were primigravid women found to have a normal cervical examination at the time of their initial prenatal visit. The remaining two patients had experienced normal outcomes in prior pregnancies. Our protocol of expectant management failed to prevent perinatal loss in these women. Three patients suffering a perinatal death had previously undergone a hysterosalpingography, and all of them had normal uterine anatomy.

Comment

The great likelihood of adverse pregnancy outcomes previously reported in diethylstilbestrol-exposed women led to the aggressive management of the patients described in this study. In a retrospective study performed at our institution Mangan et al.[11] found an increased incidence of prematurity, premature cervical dilatation, and premature rupture of membranes. Only 75% of diethylstilbestrol-exposed patients had a successful pregnancy versus 89.6% of controls. The primigravid diethylstilbestrol-exposed woman presents the most difficult problem in predicting perinatal outcome. A review of the literature reveals rates of adverse pregnancy outcome as high as 44%, prematurity rates ranging from 15.2% to 28%, and a perinatal death rate between 4% and 6% in these women.[1] These percentages are much higher than expected in the general population. The mean gestational age for primigravid patients in our study was 29.9 years of age, reflecting the time period when diethylstilbestrol was commonly prescribed (1940 to 1971). As some of these women are reaching later reproductive years, a concern is that awaiting recurrent pregnancy loss before identifying their pregnancies as high risk may be inadvisable.

The liberal use of cerclage as part of our protocol for the patient with a history of prior second-trimester loss is generally accepted in the literature, based on studies describing true cervical incompetence in these patients and successful pregnancies after cerclage. There are few prospective double-blind randomized studies concerning the use of cerclage in the nondiethylstilbestrol-exposed population.[12] Most studies are retrospective, and criteria for accurate diagnosis of incompetent cervix are difficult to define.[13] Frequently the diagnosis of incompetent cervix can be made only after a history of painless dilatation in the second trimester. In our study weekly cervical examination failed to predict second-trimester perinatal loss in five of 37 (15%) patients who did not have a prior history of second-trimester loss or hypoplastic cervix. These results emphasize that careful clinical evaluation alone may be inadequate in preventing pregnancy wastage in the diethylstilbestrol-exposed woman.

Ultrasound has been advocated as an objective way of securing the diagnosis of incompetent cervix.[14] However, several artifacts may interfere with sonographic imaging of the cervix in pregnancy.[15] These include bladder distention and angulation of and manual pressure on the transducer. As most studies have included the transabdominal approach, it remains possible that placement of a perineal or vaginal transducer may offer better imaging results.

The etiology of incompetent cervix is poorly understood. Buckingham et al.[16] first described decreased amounts of collagen and a greater percentage of smooth muscle in cervical biopsies obtained from patients with a history of cervical incompetence. To date there are few biochemical or anatomic studies of the cervical stroma in humans. Cousins[17] described a greater percentage of smooth muscle in the cervical stroma of a uterus obtained at hysterectomy in a diethylstilbestrol-exposed patient with a history of incompetent cervix. Laboratory experiments have revealed stromal changes in the endometrium of diethylstilbestrol-exposed mice, with destruction of collagen fibrils. Preliminary observations in our laboratory (J. L.) have demonstrated a decreased amount of collagen and a disarray of collagen fibrils in the cervices of diethylstilbestrol-exposed nonpregnant women.

A hypoplastic cervix cannot be equated with an incompetent cervix; however, a hypoplastic cervix has been associated with an increased risk for adverse pregnancy outcome.[11] For this reason we elected to perform a cerclage in these women. No complications were associated with placement of the cerclage except for three minor cervical lacerations at the time of delivery that were easily repaired. Although we clearly recognize the potential for selection bias in the group of women undergoing cerclage, the finding that most of these patients reached term without perinatal loss strongly suggests a benefit from our management approach. A randomized, controlled study to assess the benefit of cerclage in diethylstilbestrol-exposed primigravid women might seem in order; however, to withhold cerclage placement from those women with obvious abnormal cervical architecture (hypoplastic cervix) does not seem justified in view of our results. A striking finding of this study is that all five perinatal losses occurred in the expectant management group. Within 1 week of a normal cervical examination three primigravidas experienced premature rupture of membranes and perinatal loss. Whether these five losses could have been prevented by early cerclage is uncertain. Until we have established better methods to predict those diethylstilbestrol-exposed pregnant women at greatest risk for second-trimester loss, we believe that an aggressive approach is justified. The excellent results achieved in our elective cerclage group suggest to us that strong consideration be given to placement of a prophylactic cerclage in the diethylstilbestrol-exposed woman, irrespective of cervical appearance or findings on hysterosalpingography.

Gestational diabetes: Insulin requirements in pregnancy

Oded Langer, M.D., Akolisa Anyaegbunam, M.D., Lois Brustman, M.D., Denise Guidetti, M.D., and Roger Mazze, Ph.D.

Bronx, New York

A prospective study of 57 women with gestational diabetes mellitus was undertaken to determine actual insulin requirements throughout pregnancy. Women were placed on a multiple injection, mixed insulin regimen and monitored their blood glucose level 6.5 ± 1 times per day using a memory-based reflectance meter to obtain verified data. A significant ($p < 0.01$) increase in total insulin dose was found during the initial treatment period (7 ± 2 days) until the target glucose range was achieved. Insulin requirements continued to significantly ($p < 0.01$) rise until 30 ± 1 gestational weeks, despite a stabilization of glucose level. Thereafter, there was no significant change (3%) in insulin requirement. A correlation of $r = 0.58$ ($p < 0.001$) for the relationship between insulin dose at the 24 and 32 weeks' gestation, and an $r = 0.99$ ($p < 0.0001$) for the relationship between insulin dose at 32 and 39 weeks' gestation was found. We concluded that an emphasis on ambulatory blood glucose control and insulin adjustments should occur in the early treatment phase of gestational diabetes. (AM J OBSTET GYNECOL 1987;157:669-75.)

Key words: Gestational diabetes mellitus, insulin requirements, verified data

The perinatal principle that early stringent and consistent metabolic control decreases fetal mortality and neonatal morbidity in gestational diabetes mellitus is well accepted.[1-4] It has been shown that near normal levels of glycemic control can be achieved through the self-monitoring of blood glucose on an ambulatory basis.[5, 6] Collection of this data allows the accurate anticipation of baseline insulin requirements, as well as any changes in insulin dose necessary to achieve and maintain normoglycemia throughout pregnancy. However, it has been reported that self-monitoring errors occur that may be resolved by the use of memory-based reflectance meters.[7, 8] Our objective was to determine the pattern of insulin requirements necessary to achieve

and maintain normoglycemia among patients with gestational diabetes mellitus by the use of memory-based meters, to assure accurate characterization of insulin requirements throughout pregnancy.

Material and methods

Identification of gestational diabetes. At our medical center all pregnant women are screened for gestational diabetes mellitus between 24 and 28 weeks' gestation. For women with known selective risk factors (obesity, age, previous infants large for gestational age [LGA], or previous gestational diabetes mellitus) screening occurs at the initial prenatal visit. Screening consists of a 50 gm oral glucose load. If the 1-hour plasma glucose value is >135 mg/dl, the patient is scheduled for a full 3-hour oral glucose tolerance test, to be administered within between 3 and 7 days. All subjects are diagnosed in accordance with the criteria established by O'Sullivan and Mahan.[9] To confirm the diagnosis of gestational diabetes mellitus, all patients are given an oral glucose tolerance test (75 gm) between 2 and 6 months postpartum. Overt diabetes (type II) is defined according to the National Diabetes Data Group criteria.[10]

Study design. A prospective study of 57 patients with gestational diabetes mellitus who required insulin throughout the course of pregnancy was undertaken. To determine the initial assignment to insulin therapy, the patient had to satisfy one of two criteria. If either the fasting plasma glucose level during the oral glucose tolerance test or the 7-day overall mean blood glucose level determined by self-monitoring (immediately after the oral glucose tolerance test) was >94 mg/dl, insulin therapy was begun.[11]

Insulin algorithm. All subjects were classified according to body mass index (weight in kg/(height (m)^2) before pregnancy as obese (index >27.3) or nonobese. Obese patients received a diet of 25 kcal/kg current body weight, and nonobese patients were prescribed a diet of 35 kcal/kg body weight. The diet was calculated according to the ADA recommendations (carbohydrate 55%, protein 20%, fat 25%) and was synchronized with the insulin dose throughout the day. The insulin dose was calculated based on 0.7 U insulin per kilogram of body weight measured in pregnancy.[12]

Human insulin was administered to all patients and was divided into three injections: (1) regular and intermediate-acting insulin in the morning, (2) regular at dinner, and (3) intermediate acting at bedtime. The standard formula for the amount of insulin prescribed was two-thirds of all insulin in the morning (2:1, intermediate acting:regular) and one-third in the evening (1:1 regular:intermediate acting). If after 3 days of self-monitoring of blood glucose levels with insulin administration the overall glycemic profile had not reached the target zone (mean 75 to 95 mg/dl), insulin was to be increased at the rate of 15% to 20% for each dose. This procedure was to be repeated with a 10% to 15% increase in overall insulin dose. Thereafter, alteration in insulin dose was based on achievement of glucose target ranges for overall (75 to 95 mg/dl), fasting (60 to 80 mg/dl), preprandial (70 to 90 mg/dl), and postprandial (<120 mg/dl) levels.

Blood glucose evaluation. After diagnosis all patients were taught the self-monitoring of blood glucose levels through the use of a reflectance meter with an onboard memory. To assure maintenance of self-monitoring skills, each patient was retested at alternate clinic visits. The onboard memory in the meter can record up to 300 readings with corresponding time and date and was used to verify the blood glucose values obtained during the self-monitoring of blood glucose levels. Meter data were transmitted to a microcomputer for calculation of hourly, daily, and periodic means, as well as display of all glucose values, frequency distribution of glucose values, and measurement of standard deviation by periods within a day. Additionally, ambulatory glucose profiles were produced to assess typical daily glycemic patterns.[13] The self-monitoring blood glucose levels protocol requested 7 tests per day while fasting, before and after eating, and at bedtime. At each biweekly clinic visit the data from the reflectance meter were offloaded into a microcomputer for analysis of ambulatory glycemia.

Method of analysis. For the purpose of analysis all data were divided into three periods: Period 1, baseline (before treatment); period 2, from initiation of treatment (when insulin administration is based on "calculated" dose) to achievement of therapeutic goal; and period 3, maintenance of target glucose level. Pearson's correlation coefficient was calculated for the relationships between insulin requirements at each period. Student's t test was used to determine whether there was a significant difference in calculated and actual insulin doses.

Results

Patient characteristics. The 57 patients with gestational diabetes mellitus participating in the study had a mean age at entry of 28 ± 4 years. Fifty-seven percent of the subjects were obese according to the prepregnancy body mass index criteria. Mean gestational age at diagnosis was 26 ± 6 weeks. Distribution of gestational age showed that the earliest two patients were discovered between 18 and 20 weeks' gestation, with an additional 11 subjects identified by 23 weeks' gestation. Most women (30) were diagnosed between 24 and 28 weeks' gestation, with the remainder diagnosed by 33 weeks' gestation. The oral glucose tolerance test results were as follows: fasting, 109 ± 17 mg/dl;

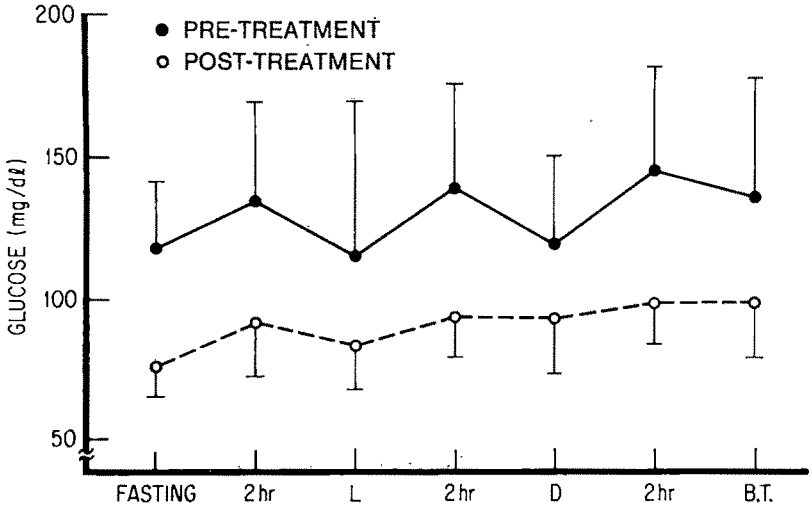

Fig. 1. Representation of glycemic control before and after treatment. This represents the metabolic control in periods I and II. *Significant difference ($p < 0.01$) before and after treatment at each time period.

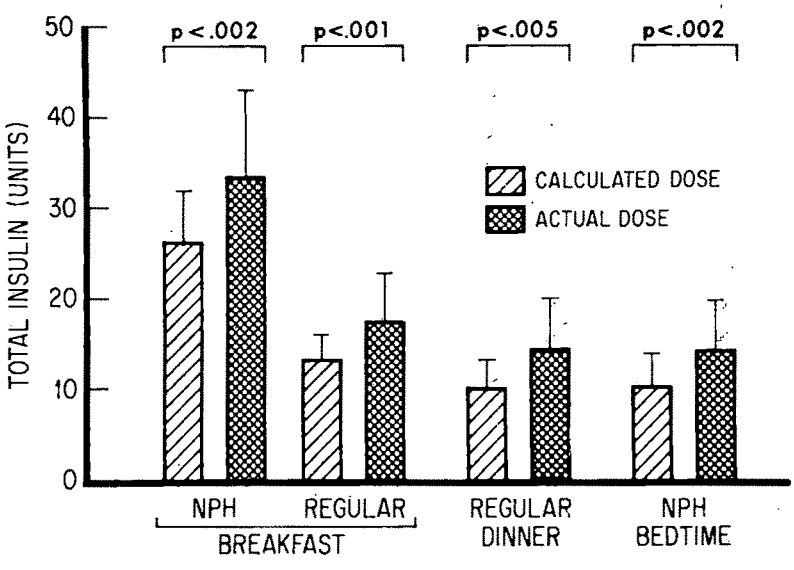

Fig. 2. Calculated versus actual insulin dose during period 2. *NPH* = Intermediate-acting insulin.

1 hour, 205 ± 33 mg/dl; 2 hours, 200 ± 43 mg/dl; and 3 hours, 148 ± 38 mg/dl. Average time of delivery was at 39 ± 2 weeks.

Postpartum evaluation by oral glucose tolerance test given between 2 and 6 months revealed no overt diabetes among the study group. The oral glucose tolerance test resulted in the following values: fasting, 99 ± 13 mg/dl; 1 hour, 156 ± 35 mg/dl; 2 hours, 122 ± 22 mg/dl, and 3 hours, 92 ± 23 mg/dl.

Period 1. Fig. 1 shows the overall level of glycemia for all study patients before the start of treatment (7 to 10 days). The mean blood glucose level was calculated as 139 ± 38 mg/dl. Variability in control was measured by the coefficient of variation (29%). In general, values after eating were higher than those before eating. Bedtime values showed the greatest deviation from the overall value. At the end of this period 52 subjects were assigned to insulin based on the oral glucose tolerance test fasting values and the mean blood glucose values for the period. Five additional patients were placed on insulin therapy due only to a mean blood glucose level >94 mg/dl for the baseline period.

Period 2. Fig. 2 shows the initially calculated insulin dose of 56 ± 10 U (based on the 0.7 U/kg formula) compared with the dose of 76 ± 14 U administered at the end of period 2 (achievement of glucose target). For the prebreakfast, predinner, and bedtime insulin doses, we found that a significantly higher amount of

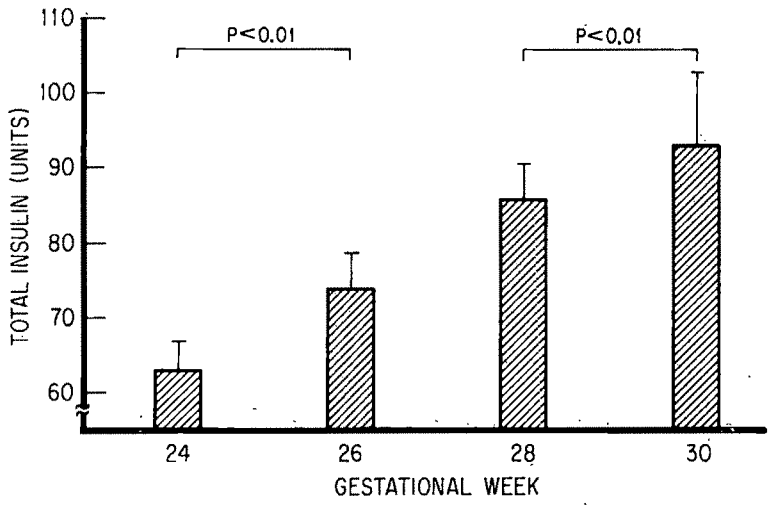

Fig. 3. Insulin requirements for 33 subjects in the early part of period 3.

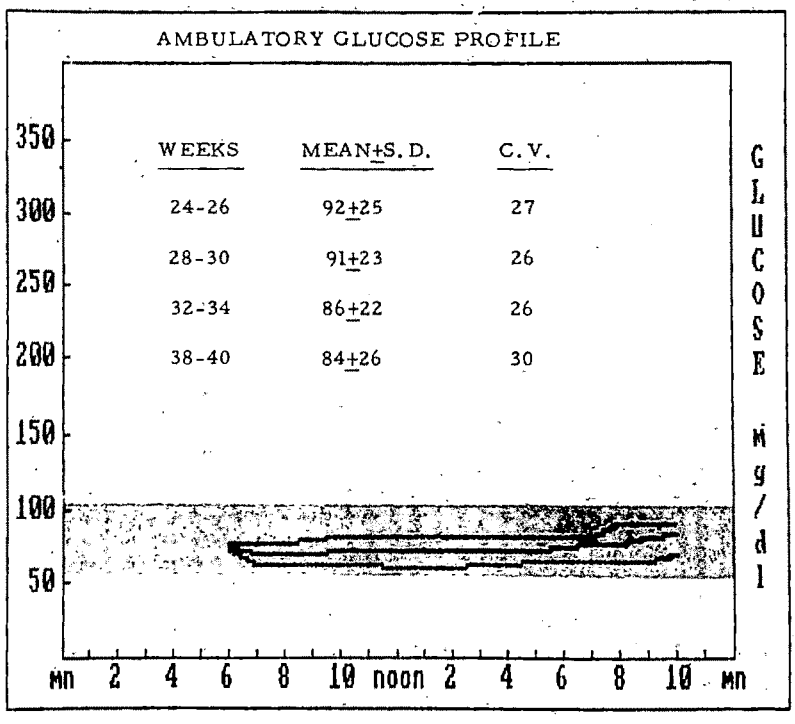

Fig. 4. Ambulatory glucose profile of patients throughout pregnancy. The computer printout from the memory-based reflectance meter summarizes the biweekly ambulatory glucose control based on self-monitoring data. The graph shows a typical pattern (from 6 AM to 10:30 PM) of gestational diabetes mellitus in treatment. The curves represent the median (middle) and variability (seventy-fifth and twenty-fifth percentiles) glucose values. The *shaded area* identifies the normal target range for glucose values throughout the day. *CV* = Coefficient of variation.

insulin was prescribed than calculated by the formula. During this period, glucose levels decreased significantly (from 139 ± 38 to 95 ± 21 mg/dl), with a comparable narrowing of variability (from 29% to 22%; Fig. 1). Summary statistics for this transitional period, which averaged 7 ± 2 days, revealed that the patients tested 6.5 ± 1 times a day and that overall insulin requirements increased by 36% ($p < 0.01$).

Period 3. Examination of the change in insulin requirements that occurred among the 33 patients who

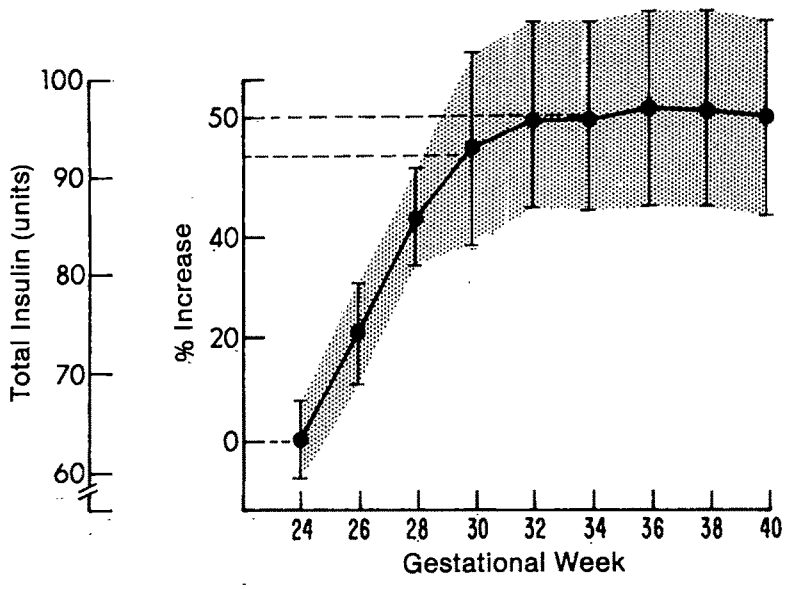

Fig. 5. Insulin requirement throughout pregnancy for 57 subjects. Total insulin required throughout pregnancy and percent increase in insulin are measured along the y axis. The period of 24 to 30 weeks' gestation shows the greatest change in absolute dose and percent, while the period from 32 to 40 weeks' gestation shows the greatest stability. The *shaded area* represents 1 SD.

Table I. Insulin requirements and correlation coefficients

	24 ± 2 versus 32 ± 3 wk			*32 ± 3 versus 39 ± 2 wk*		
	r	R^2	*p*	*r*	R^2	*p*
Morning						
Intermediate-acting	0.60	0.36	<0.001	0.98	0.97	<0.0001
Regular	0.55	0.30	<0.005	0.99	0.98	<0.0001
Evening						
Regular	0.63	0.40	<0.001	0.80	0.64	<0.0001
Intermediate-acting (10 PM)	0.47	0.22	<0.02	0.99	0.98	<0.0001

were at 24 ± 2 weeks, gestational age at entry into period 3 revealed a constant increase in insulin dose to maintain the target blood glucose levels. This increase was significant between 24 to 26, 26 to 28, and 28 to 30 weeks' gestation (Fig. 3). Overall insulin requirements increased by 47% during the early part of period 3. Regression analysis revealed a correlation ($r = 0.57$; $p < 0.001$) between the predictability of the 32 weeks' gestation insulin dose from the 24 week insulin dose. This association was shown to occur for each type of insulin. The fasting, preprandial and postprandial, and bedtime glucose levels did not significantly change during this period. Overall metabolic control was calculated as 92 ± 25 mg/dl in the early part of period 3.

Examination of the change in insulin requirements during the latter half of period 3, when all 57 subjects achieved the target glucose range, revealed an average blood glucose level of 91 ± 23 mg/dl, which did not significantly change throughout this period. Analysis by ambulatory glucose profile of daily glycemic control for all patients showed that blood glucose values remained within a narrow target range, with no significant excursions throughout the day (Fig. 4). Furthermore, we found no significant increase in insulin requirements during this time (Fig. 5). There was a strong positive correlation ($r = 0.99$; $p < 0.0001$) between the overall insulin dose at 32 and 40 weeks' gestation. Additionally, a correlation of $r = 0.99$ ($p < 0.0001$) was calculated for the predictability of morning insulin requirements and $r = 0.80$ to 0.99 ($p < 0.0001$) for evening insulin requirements when the thirty-second and thirty-ninth weeks were examined. $r = 0.62$ ($p < 0.001$) for regular insulin at dinner (Table I).

We then examined the different insulin requirements for the obese (body mass index >27.3) and nonobese study subjects. For the obese subjects and actual insulin requirements were 0.8 U/kg and for the nonobese sub-

jects it was 0.9 U/kg, with no significant difference between them. However, there was a significant difference in variability, as measured by the coefficient of variation (45% versus 25%; $p < 0.01$).

Comment

Gestational diabetes mellitus is a disease whose characteristic is carbohydrate intolerance with first onset or recognition during pregnancy.[14] It encompasses a heterogeneous array of insulin secretion and action disorders that manifest themselves in varying levels of metabolic control. The clinical importance of gestational diabetes mellitus lies in its relationship to adverse perinatal and neonatal outcome (mainly macrosomia and stillbirth) when these individuals are not treated or are maintained in poor metabolic control; in its masking of pregestational diabetes; and in an increased risk of developing type II diabetes.

Two features of the current study make it unique. First, it included women with gestational diabetes mellitus characterized by varying degrees of carbohydrate intolerance and shown postpartum not to have overt (type II) diabetes. With these subjects we were able to evaluate the insulin requirements needed to achieve near-normal levels of glycemic control in gestational diabetes mellitus. Second, utilization of memory-based reflectance meters (providing verified blood glucose data) permitted us to characterize ambulatory glycemic control throughout the pregnancy. This, in turn, enabled us to aggregate glucose data efficiently and evaluate the level of glycemic control and its association to insulin requirements throughout the pregnancy of patients with gestational diabetes mellitus.

Our study revealed that normoglycemia in women with gestational diabetes could be achieved and maintained for prolonged periods in ambulatory prenatal care. The achievement and maintenance of near-normal glycemia was possible by accurately predicting the pattern of insulin requirement and individual insulin adjustments throughout the course of gestational diabetes.

Although the role of insulin requirement in pregestational diabetes (types I and II) was previously studied,[12, 15] its role in gestational diabetes is not well established. In individuals with type II diabetes, there is an almost linear rise in insulin dose between the second and the ninth months, with a twofold increase in daily insulin requirement.[16] In contrast, we found that patients with gestational diabetes mellitus have a gradual and significant increase in insulin requirements until the thirtieth week of gestation and thereafter stabilization occurs. Furthermore, during the latter half of the third trimester (30 to 39 weeks) the variability in insulin dose remains unchanged. Additionally, we found that the total insulin dose for subjects with gestational diabetes mellitus (91 ± 10 U) was greater than the total dose previously reported for individuals with type I diabetes (70 ± 18 U).

As with any type of therapy, the potential benefits of treatment must be weighed against the potential risks. For instance, the selection of a threshold for insulin administration (>94 mg/dl) was predicated on our earlier study, which showed a high incidence of macrosomia when diet-only regimens were prescribed to patients with fasting plasma glucose levels between 95 and 105 mg/dl.[11] Furthermore, we noted that the standard "calculated" insulin dose at the start of treatment had to be significantly increased to reach the target glycemic range. Despite the potential for low blood glucose levels when insulin administration is used to tighten metabolic control, no episodes of hypoglycemia occurred in any of the patients during this period.

The calculated dose (0.7 U/kg), based on previous studies[12, 16] of the insulin requirements in pregestational diabetes (type I), provided an appropriate starting point for insulin administration, because it improved control within two adjustments without the risk of hypoglycemia. Consequently, we were able to identify an algorithm that provided an appropriate and safe method of rapidly achieving the target glucose range.

We found that the relative instability in glucose metabolism could only be corrected with increasing levels of insulin during period 2 and the early stages of period 3. Once glucose metabolism stabilized, insulin dosage remained relatively constant. Thus we conclude that frequent clinic visits and adjustments in insulin doses are mandatory for accurate clinical decision-making during the early stages of gestational diabetes mellitus. This in turn will, we suspect, decrease adverse perinatal and neonatal outcomes. Additionally, we noted that in the late stage of period 3, virtually no variation in insulin requirements exists. This suggests that a less pronounced effort is required for maintaining the adherent patient in good metabolic control during this period.

Our data suggest that the mechanism by which insulin requirements change may be related to human placental lactogen secretion, because the insulin dose and human placental lactogen curves coincide. They both tend to rise in the second trimester and plateau at 32 to 35 weeks' gestation. Because human placental lactogen has been identified as a major diabetogenic factor in pregnancy, it is reasonable to assume that the glucose profile would be affected in gestational diabetes mellitus. Therefore, the identification of gestational diabetes mellitus may occur as early as 18 weeks' gestation and as late as 35 weeks.

In summary, the main changes in insulin requirements are evident before 30 weeks' gestation; these requirements do not increase thereafter; and the em-

phasis on ambulatory self-monitoring of blood glucose levels and readjustment of the insulin dose should be maximized within this interval.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Status of infants at birth and risk for adverse neonatal events and long-term sequelae: A study in low birth weight infants

David A. Luthy, M.D., Kirkwood K. Shy, M.D., M.P.H., Daniel Strickland, Ph.D., Judy Wilson, R.N., Forrest C. Bennett, M.D., Zane A. Brown, M.D., and Thomas J. Benedetti, M.D.

Seattle, Washington

We evaluated the relationship of infant status at birth to neonatal morbidity and long-term development in 246 low birth weight infants (600 to 1750 gm). Nineteen percent of infants had 1-minute Apgar scores of ≤3, and 8% had an umbilical artery pH of ≤7.2. Acidosis was associated with an increased risk of grade 3 to 4 intracranial hemorrhage (odds ratio = 3.3). Low 1-minute Apgar score was associated with an increased risk of death (odds ratio = 4.8). Grade 3 to 4 intracranial hemorrhage was a strong risk factor for cerebral palsy among survivors (odds ratio = 16.1), as was low 1-minute Apgar score (odds ratio = 2.9). Only 15% of cases of cerebral palsy in this study were associated with acidosis at birth. (Am J Obstet Gynecol 1987;157:676-9.)

Key words: Apgar score, cord artery pH, intracranial hemorrhage, cerebral palsy

The relationship of intrapartum events to infant status at birth and subsequent neonatal and infant morbidity remains controversial. Although the available data have been reviewed recently,[1] this publication dealt primarily with term infants. Since infants of low birth weight are at high risk for adverse outcomes, the present study was undertaken to evaluate the relationship of infant status at birth to the risk for neonatal mortality and morbidity, including abnormal development.

Material and methods

The study was conducted at the University of Washington, Seattle, and Grace Hospital, Vancouver, British Columbia, Canada, from November 1981 to March 1, 1985.

The study group consisted of 246 low birth weight infants weighing from 600 to 1750 gm. These infants were all singleton, in cephalic presentation, and products of premature labor at 26 to 32 weeks' gestation. Multiple pregnancy, noncephalic presentation, antenatal hemorrhage, recognizable malformations, and infants delivered before the onset of labor were excluded from the study. All patients were part of a prospective study of electronic fetal heart rate monitoring that included care by a study nurse on a one-to-one basis. Labors were managed by house officers with attending physician supervision. Protocols used for fetal heart rate monitoring and labor are described in detail elsewhere.[2]

One-minute Apgar scores and umbilical cord arterial pH were used as indicators of the infant status at birth. At the time of delivery, 1- and 5-minute Apgar scores were assigned by the senior pediatrician in attendance. A 1-minute Apgar score of ≤3 was considered to be significant neonatal depression. A doubly clamped segment of umbilical cord was obtained for complete blood gas analysis. An umbilical cord arterial pH of ≤7.20 was considered to indicate acidosis. This value was chosen because a scalp pH of ≤7.20 would have prompted immediate delivery by the labor management protocol in use during this study.[2] At 76 to 92 hours of age, all infants underwent a cranial ultrasound examination to detect intracranial hemorrhage. Intracranial hemorrhage was graded 1 to 4 according to severity.[3] At 4, 8, and 18 months' corrected age, survivors of the neonatal period had developmental testing, by means of the Bayley scale of infant development.[4] At 18 months' corrected age, developmental pediatricians classified infants as either definitely having cerebral palsy or not having cerebral palsy.

Correlation coefficients were calculated to assess the association between Apgar score, cord arterial pH, and birthweight. Odds ratios and 95% confidence limits were used to estimate risk of adverse infant status at birth for late neonatal and infant morbidity. The χ^2 analysis was used to test for statistical significance. Since birth weight was a confounding variable, a logistic regression was used to control for birth weight in the

analysis. However, odds ratios, both crude and adjusted for birth weight, are given for comparison. Simultaneous control of Apgar score and umbilical artery pH did not change the risk estimate significantly for any of the outcome measures (intracranial hemorrhage, death, cerebral palsy) analyzed.

Results

There were 35 deaths (14%) among the 246 infants studied. One hundred ninety-nine infants (80%) had cord blood gas analysis performed at the time of delivery. There were 212 surviving infants. Of those, 187 (88%) had at least one follow-up examination.

There was a statistically significant but low association between birth weight and 1-minute Apgar score ($r = 0.4$, $p < 0.0001$). There was a lower but also statistically significant association between birth weight and umbilical cord arterial pH ($r = 0.23$, $p < 0.0001$).

Among the 199 infants who had umbilical cord blood gas analysis performed, the association between umbilical cord arterial pH and 1-minute Apgar score was statistically significant but not strong ($r = 0.23$, $p = 0.001$). Overall, 19% of infants had a 1-minute Apgar score of ≤3 and 8% of infants had an umbilical cord arterial pH of ≤7.20. Seventy-five percent of the 199 infants had 1-minute Apgar scores >3 and umbilical artery pH >7.20. Two percent of infants had a depressed Apgar score at 1 minute and a low cord artery pH. Only 10% of low Apgar scores were associated with an umbilical cord arterial pH of ≤7.20, whereas 75% of acidotic infants (12 of 16) were not depressed at birth (Table I).

Overall, 36 of 246 infants (15%) developed grade 3 to 4 intracranial hemorrhage (Table II). Twenty-six percent of infants (19 of 73) with 1-minute Apgar scores of ≤3 developed grade 3 to 4 intracranial hemorrhage

compared with 10% (17 of 174) of infants with 1-minute Apgar scores >3 (crude odds ratio = 3.3, 95% confidence interval = 1.5 to 7.1; adjusted odds ratio = 1.5, 95% confidence interval = 0.6 to 3.3). The odds ratio is not statistically significant when adjusted for birth weight. Of the infants who had cord blood gas analysis, 23 of 199 (12%) developed grade 3 to 4 intracranial hemorrhage (Table III). Thirty-five percent (seven of 20) of infants with an umbilical cord arterial pH of ≤7.20 had grade 3 to 4 intracranial hemorrhage, compared with 9% (16 of 179) of those with a cord arterial pH >7.20 (crude odds ratio = 5.5, 95% confidence interval = 1.6 to 17.3; adjusted odds ratio = 3.3, 95% confidence interval = 1.1 to 10.3). The odds ratio is statistically significant when adjusted for birth weight.

A strong correlation was found between the risk of death and 1-minute Apgar score of ≤3. Thirty-six percent of infants (26 of 73) with low Apgar scores at 1 minute died, compared with 5% (nine of 174) of those infants with 1-minute scores >3 (crude odds ratio = 10.1, 95% confidence interval = 4.2 to 25.2; adjusted odds ratio = 4.8, 95% confidence interval = 1.8 to 11.9). Twenty-five of 199 infants (13%) who had cord blood gas analysis died. Thirty percent (six of 20) of infants with an umbilical artery pH of ≤7.2 died, compared with 11% of those with an umbilical artery pH >7.2 (crude odds ratio = 3.6; 95% confidence interval = 1.0 to 11.5; adjusted odds ratio = 1.8; 95% confidence interval = 0.6 to 6.1).

After the 18-month infant examination, there were 23 cases of cerebral palsy among the 187 infants (12%) who had developmental testing. Twenty percent of infants (nine of 45) with a 1-minute Apgar score of ≤3 developed cerebral palsy, compared with 10% (14 of 142) of those with 1-minute Apgar scores >3 (crude odds ratio = 2.6, 95% confidence interval = 1.0 to 6.9; adjusted odds ratio = 2.9, 95% confidence interval = 1.1 to 7.9). Twenty-one percent of infants (three of 14) with an umbilical artery pH of ≤7.20 developed cerebral palsy, compared with 11% of infants (16 of 142) with an umbilical artery pH >7.20 (crude odds ratio = 2.3, 95% confidence interval = 0.4 to 10.3; adjusted odds ratio = 2.6, 95% confidence interval = 0.6 to 11.0).

The risk of cerebral palsy was most strongly associated with grade 3 to 4 intracranial hemorrhage (Table IV). Thirteen percent of surviving infants who had developmental testing (25 of 187) had a grade 3 to 4

intracranial hemorrhage. Forty percent of surviving infants (10 of 25) with grade 3 to 4 intracranial hemorrhage developed cerebral palsy, compared with 8% (13 of 162) of those without grade 3 to 4 intracranial hemorrhage (crude odds ratio = 8.3, 95% confidence interval = 3.2 to 22.0; adjusted odds ratio = 16.1, 95% confidence interval = 4.6 to 57.1).

Comment

Our study was composed of premature infants (26 to 32 weeks) of low birth weight (600 to 1750 gm). Premature infants with birth weights in this range are known to be at high risk for neonatal morbidity or death as well as abnormal development, when compared with term infants of normal birth weight. Few studies, especially of low birth weight infants, have longitudinally evaluated infants from birth with cord blood gas data, cranial ultrasound examinations, and developmental testing. Since study design excluded many pregnancies with antenatal risk factors, our study population consisted primarily of patients with idiopathic premature labor, including premature rupture of the membranes. Thus the infant's status at birth in our study may have been less affected by antenatal factors than would have been true in a cross-sectional study of all premature infants.

While one in five infants had a 1-minute Apgar score of ≤3, fewer than one in 10 infants had an umbilical cord artery pH of ≤7.20. The correlation between 1-minute Apgar score and umbilical artery pH, while statistically significant in our study, was not a strong association. Others have noted the low association between Apgar scores and umbilical artery pH in term infants[5] as well as preterm infants.[6] Only 10% (four of 38) of low Apgar scores in our study were associated with acidosis. The term perinatal asphyxia is frequently applied to infants with low Apgar scores, especially when umbilical gas data are not available. The results of our study, as well as others,[5,6] suggest that this practice is inaccurate, at the least, for both term and premature infants. We suggest the term perinatal asphyxia should be used only with biochemical evidence of same.

A low 1-minute Apgar score was associated with almost a fivefold increased risk for death when adjusted for birth weight. In 75% of all deaths in our study, the 1-minute Apgar score was ≤3. Neonatal depression was a strong risk factor for death, but this was not related to acidosis. This risk remained after adjustment for birth weight; thus the lowering of Apgar scores that resulted from very small infants cannot be the explanation. Generalized central nervous system depression at birth could explain the lack of correlation with acidosis as well as the increased risk for death in these infants; however, this hypothesis cannot be evaluated with the available data.

Acidosis (cord artery pH < 7.20) was associated with a threefold increased risk for grade 3 to 4 intracranial hemorrhage, an association unlikely to be due to chance or differences in birth weight. However, this accounted for only 30% of all cases of grade 3 to 4 intracranial hemorrhage in our study. We noted a trend toward increasing risk of intracranial hemorrhage with worsening acidosis. The risk of grade 3 to 4 intracranial hemorrhage was 50% in our study if the cord artery pH was ≤7.15; if the pH was 7.15 to 7.20, the rate was the same as in infants with an umbilical artery pH >7.20.

Grade 3 to 4 intracranial hemorrhage was the strongest risk factor for cerebral palsy. More than 40% of infants with cerebral palsy in our study had a major intracranial hemorrhage. Infants with grade 3 to 4 intracranial hemorrhage had a sixteenfold increased risk for cerebral palsy, when adjusted for birth weight, compared with infants with grade 1 to 2 intracranial hemorrhage or without intracranial hemorrhage. Low 1-minute Apgar score was also associated with a statistically significant risk (almost threefold) for cerebral palsy. While a statistically significant correlation between acidosis and cerebral palsy could not be demonstrated, given the strong association between acidosis and intracranial hemorrhage and between intracranial hemorrhage and cerebral palsy, our study may not have been large enough to detect a true difference. However, most cases of cerebral palsy in our study of premature infants were unrelated to acidosis at birth. Only 15% of the cases of cerebral palsy in our study were associated with an umbilical artery ≤pH of 7.20. This suggests that factors other than birth asphyxia may have important roles in the causes of cerebral palsy among premature infants, and our data are in agreement with the concept that cerebral palsy has multifactorial causes in premature infants.

A classification of hypertension in pregnancy based on Doppler velocimetry

James Ducey, M.D., Harold Schulman, M.D., George Farmakides, M.D., Burton Rochelson, M.D., Luis Bracero, M.D., Adiel Fleischer, M.D., Edwin Guzman, M.D., Denise Winter, R.N., B.S.N., and Barbara Penny, R.N.

Mineola, Stony Brook, Westchester, and Bronx, New York

We studied 136 pregnant women with hypertension with Doppler velocimetry of the uterine and umbilical arteries. The patients were classified into four groups according to the values of the systolic/diastolic ratios. The first group had normal ratios in both the umbilical and uterine arteries. The second group had elevated umbilical ratios and normal ratios in the uterine arteries. The third group had elevated uterine artery systolic/diastolic ratios with normal umbilical artery values, and the fourth group had elevated systolic/diastolic ratios in both vessels. Women in the group with normal ratios in both the umbilical and uterine arteries were delivered of infants with a birth weight (means ± SD) of 3261 ± 522 gm and gestational age of 39 ± 2 weeks. The values for the three groups with abnormal velocimetry were: those with elevated umbilical ratios and normal ratios in the uterine arteries: body weight = 2098 ± 811 gm, gestational age = 35.7 ± 3.2 weeks; those with elevated uterine artery ratios with normal umbilical artery values: 2464 ± 722 gm, gestational age = 36.3 ± 3 weeks; and those with elevated systolic/diastolic ratios in both vessels: body weight = 1627 ± 697 gm, gestational age = 33.3 ± 2.7 weeks ($p < 0.01$; $p < 0.001$). There were 27 small for gestational age infants delivered during this study. Doppler velocimetry studies were abnormal in 26 of them (96%). Results show that Doppler-derived vascular patterns correlate well with normal and adverse perinatal outcome. A description of the uterine and umbilical systolic/diastolic ratios should be part of the clinical evaluation of all pregnant women with hypertension. This should lead to better treatment protocols and improved clinical outcome. (Am J Obstet Gynecol 1987;157:680-5.)

Key words: hypertension, pregnancy, Doppler

Hypertensive disorders in pregnancy are difficult to distinguish. In many diseases hypertension can be a manifestation in women in the reproductive age group. Their effect on pregnancy is variable. The rates of preterm birth, small for gestational age infants, and perinatal death are increased in pregnancies complicated by hypertension.[1, 2] According to current recommendations, all pregnant women with hypertension undergo serial ultrasonographic examinations and weekly fetal heart rate testing or biophysical profiles to identify the fetus at risk for hypoxia and acidosis.[3] Elective preterm delivery is frequently advocated for hypertensive women in an attempt to improve neonatal outcome, although this frequently incurs the risks of cesarean section and prematurity.

Hypoxic complications in fetuses of hypertensive women are thought to be the result of vascular lesions in the utero-placental circulation with resultant decrease in blood flow.[4] Doppler velocimetry is a technique that is useful for assessing blood flow and vascular resistance and thereby offers the promise of better defining the fetal and maternal risk in pregnancy hypertensive syndromes.[5-7]

The purpose of this study was to examine Doppler velocimetry of the umbilical and uterine arteries in women whose pregnancies were complicated by hypertension. Women were classified by vascular patterns. Results show that Doppler-derived vascular patterns correlate well with normal and adverse perinatal outcome.

Material and methods

One hundred thirty-six women seen in the antepartum testing units of Winthrop-University Hospital, Stony Brook University Hospital, Bronx Municipal Hospital Center, and Westchester County Medical Center because of hypertension make up the sample studied. Doppler waveforms were obtained from the uterine and umbilical arteries. The equipment used was the Angioscan (Ultrasonix, Mt. Vernon, New York) or the Multigon 500 A (Multigon Industries, Mt. Vernon,

New York) spectral analyzer. These are continuous-wave Doppler systems. The maximum Doppler shift during systole is divided by the maximum shift during end diastole to give the systolic/diastolic ratio.[8, 9]

Pattern recognition was used to identify the waveforms as being uterine or umbilical. The umbilical artery was studied from at least three different angles and the systolic/diastolic ratios were averaged. Two readings of each uterine artery were recorded and averaged at each study.

Women were studied serially from time of referral until time of delivery. The majority of women underwent two or more studies. The reported values are the mean umbilical artery systolic/diastolic ratio after 30 weeks and the mean uterine artery systolic/diastolic ratio after 26 weeks. An average umbilical systolic/diastolic ratio of 3.0 or more after 30 weeks was used as a cutoff. We have used this value as the most sensitive and specific for the detection of intrauterine growth retardation.[9] The mean uterine systolic/diastolic ratio from 26 weeks to term is 2.0 with an SD of 0.3, and once again the data in this series corroborate this figure (Table I). The mean umbilical systolic/diastolic ratio after 30 weeks in a normal population is 2.4 with an SD of 0.3, which is the same as that of the group with normal ratios in both the umbilical and uterine arteries in this series (Table II). A uterine systolic/diastolic ratio >2.6 after 26 weeks had previously been shown to be associated with adverse perinatal outcome[10] (Figs. 1 and 2).

Patients were then divided into four groups based on velocimetry: (1) those with normal uterine and umbilical artery systolic/diastolic ratios, (2) those with normal uterine artery systolic/diastolic ratios and abnormal umbilical artery systolic/diastolic ratios, (3) those with normal umbilical artery systolic/diastolic ratios and abnormal uterine artery systolic/diastolic ratios, and (4) those in whom both systolic/diastolic ratios were abnormal.

The patients were also classified by clinical diagnosis. Chronic hypertension was defined as a mean arterial pressure of >90 mm Hg at 20 weeks. Pregnancy-induced hypertension was defined as a rise in systolic blood pressure >30 mm Hg or the diastolic blood pressure >15 mm Hg over the first trimester blood pressure determinations that persisted after 6 hours of bed rest. Preeclampsia was diagnosed when pregnancy-induced hypertension was accompanied by proteinuria (>300 mg in a 24-hour urine collection or >3+ on dipstick). If the patient's prenatal records were not available, the attending physician's discharge diagnosis was taken as the clinical diagnosis.

An abnormal nonstress test result was defined as a fetal heart rate score of 7 or less.[11] Small for gestational age diagnosis was defined as ≤the tenth percentile, Denver classification.

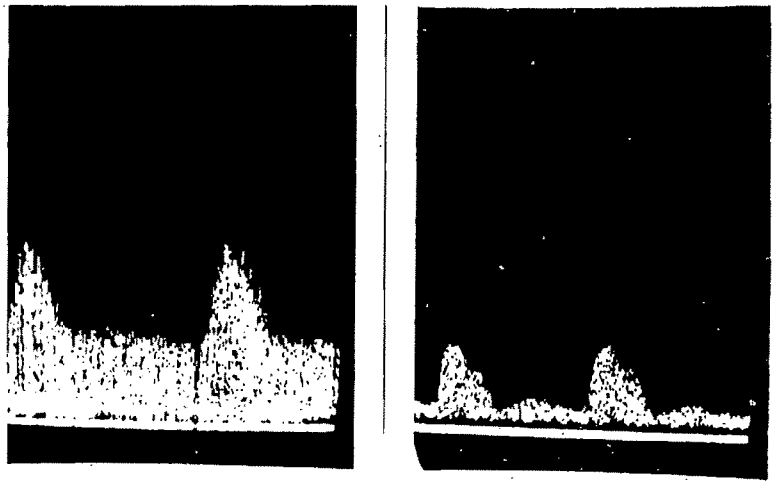

Fig. 1. Doppler images of uterine artery waveforms. (*S/D*, systolic/diastolic.)

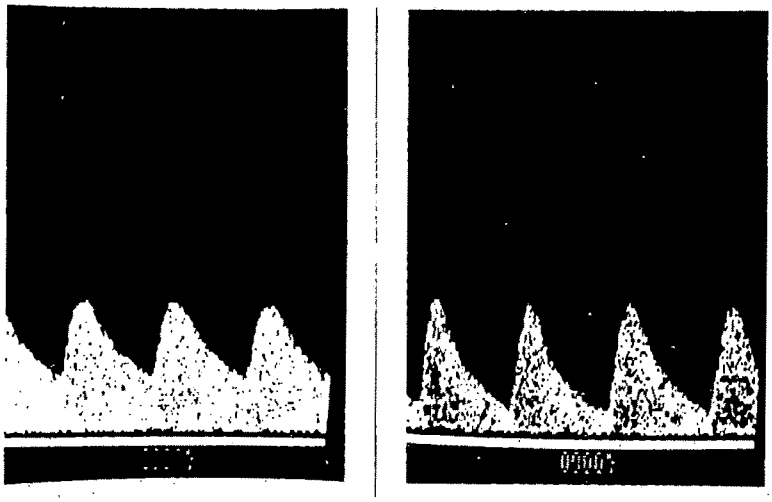

Fig. 2. Doppler images of umbilical artery waveforms. (*S/D*, systolic/diastolic.)

All patients were managed by attending physicians or house staff with faculty supervision. The results of the Doppler studies were not used to influence clinical management.

Results

The various maternal parameters studied are listed in Table I. There was no difference in age, percentage of nulliparous women, or mean arterial pressure in the second trimester between the four groups. Thrombocytopenia was present in 26% of the group with normal uterine and abnormal umbilical artery ratios ($p < 0.05$) and 13% of the group with normal umbilical and abnormal uterine artery ratios (p not significant). It was not seen in the groups with normal uterine and umbilical artery ratios and those in whom both ratios were abnormal.

The mean uric acid level for the group with normal

	n	*Nn (n = 58)* (%)	*Na (n = 27)* (%)	*An (n = 12)* (%)	*Aa (n = 31)* (%)
Chronic hypertension	43	65	23	5	7
PIH	34	59	15	6	21
Preeclampsia	51	20	24	16	41

Nn, group with normal uterine and umbilical artery ratios; Na, group with normal uterine and abnormal umbilical artery ratios; An, group with normal umbilical and abnormal uterine artery ratios; Aa, group in whom both ratios were abnormal; PIH, pregnancy-induced hypertension.

uterine and umbilical artery ratios was 5.6. For the groups with normal uterine and abnormal umbilical artery ratios, those with normal umbilical and abnormal uterine artery ratios, and those in whom both ratios were abnormal the values were 6.5, 6.0, and 6.5, respectively. Although there appears to be a trend toward higher levels, there was a great deal of overlap among the individual values between all four groups. The only group in whom statistical significance was reached was the group in whom both ratios were abnormal.

Proteinuria was present in 24% of women in the group with normal uterine and umbilical artery ratios, 71% of those in the group with normal uterine and abnormal umbilical artery ratios, 75% of those in the group with normal umbilical and abnormal uterine artery ratios, and 86% of those in the group in whom both ratios were abnormal. A total of 77 women had proteinuria in this study sample. Sixty-one of them (77%) had abnormal Doppler velocity waveforms of the uterine or umbilical arteries.

The clinical condition of mother or fetus led to intervention in many of these pregnancies. In the normal-normal group, this occurred in one third of the women. It occurred 58% of the time in patients with normal uterine and abnormal umbilical artery ratios and those with normal umbilical and abnormal uterine artery ratios ($p < 0.05$) and 74% of the time when both ratios were abnormal ($p < 0.001$). In the latter group the predominant indication was an abnormal antepartum fetal heart rate pattern.

There were two cases of eclampsia seen during this study. Both of those women were in the group with normal uterine and abnormal umbilical artery ratios.

Table II summarizes fetal parameters studied. The birth weights and gestational ages of the four groups were as follows (means ± SD): group with normal uterine and umbilical artery ratios, 3261 ± 522 gm and 39 ± 2 weeks; group with normal uterine and abnormal umbilical artery ratios, 2098 ± 811 gm and 35.7 ± 3.2 weeks; group with normal umbilical and abnormal uterine artery ratios, 2464 ± 722 gm and 36.3 ± 3 weeks; and those in whom both ratios were abnormal, 1627 ± 697 gm and 33.2 ± 2.7 weeks. The incidence of preterm delivery in the four groups was as follows: group with normal uterine and umbilical artery ratios, 11%; group with normal uterine and abnormal umbilical artery ratios, 61%; group with normal umbilical and abnormal uterine artery ratios, 67%; and those in whom both ratios were abnormal, 84%.

Fetuses of women with abnormal uterine or umbilical systolic/diastolic ratios weighed less and were delivered earlier than those whose mothers had normal values. One neonate was small for gestational age in the group with normal uterine and umbilical artery ratios (2%). This infant was delivered normally at 40 weeks and weighed 2000 gm. The infant had no problems in the neonatal period. Twenty-nine percent ($p < 0.01$) of fetuses in the group with normal uterine and abnormal umbilical artery ratios were small for gestational age. Seventeen percent (p not significant) of fetuses in the group with normal umbilical and abnormal uterine artery ratios were small for gestational age and 51% ($p < 0.001$) of fetuses in those in whom both ratios were abnormal were small for gestational age.

Overall 27 small for gestational age infants were delivered during this study. Doppler velocimetry of either the umbilical or uterine arteries was abnormal in 26 of them (96%).

Fetal distress in labor occurred in 8% of the group with normal uterine and umbilical artery ratios, 39% ($p < 0.01$) of the group with normal uterine and abnormal umbilical artery ratios, 8% (p not significant) of the group with normal umbilical and abnormal uterine artery ratios, and 62% ($p < 0.001$) of those in whom both ratios were abnormal.

Twelve percent of neonates delivered of women in the group with normal uterine and umbilical artery ratios required admission to the neonatal intensive care unit and the percentages of the group with normal uterine and abnormal umbilical artery ratios, group with normal umbilical and abnormal uterine artery ratios, and those in whom both ratios were abnormal, respectively, were 68% ($p < 0.001$), 50% ($p < 0.05$), and 89% ($p < 0.001$).

There were four perinatal deaths during the study, two stillbirths and two neonatal deaths. The mothers of these were all in those in whom both ratios were abnormal.

Nonstress tests were abnormal in 12% of women in group with normal uterine and umbilical artery ratios, 15% in group with normal uterine and abnormal umbilical artery ratios, 11% in group with normal umbilical and abnormal uterine artery ratios, and 78% in those in whom both ratios were abnormal.

Creatinine clearance and fibrinogen levels were also studied. For group with normal uterine and umbilical artery ratios they were (means ± SD) 119 ± 35 ml/min and 485 ± 109 mg/dl; group with normal uterine and abnormal umbilical artery ratios, 85 ± 44 ml/min and 361 ± 121 mg/dl; group with normal umbilical and abnormal uterine artery ratios, 107 ± 30 ml/min and 408 ± 44 mg/dl; and those in whom both ratios were abnormal, 89 ± 34 ml/min and 378 ± 122 mg/dl. None of these values show a difference that is statistically significant.

Table III compares vascular pattern with clinical diagnoses. Forty-three women had chronic hypertension. Sixty-five percent ($p < 0.001$) of them were in the group with normal uterine and umbilical artery ratios, 23% in the group with normal uterine and abnormal umbilical artery ratios, 5% in the group with normal umbilical and abnormal uterine artery ratios, and 7% in those in whom both ratios were abnormal. Thirty-four women had pregnancy-induced hypertension. Fifty-nine percent ($p < 0.001$) were in group with normal uterine and umbilical artery ratios, 15% in group with normal uterine and abnormal umbilical artery ratios, 6% in group with normal umbilical and abnormal uterine artery ratios, and 21% in those in whom both ratios were abnormal. Fifty-one women had preeclampsia. Twenty percent were in the group with normal uterine and umbilical artery ratios, 24% in the group with normal uterine and abnormal umbilical artery ratios, 16% in the group with normal umbilical and abnormal uterine artery ratios, and 41% in those in whom both ratios were abnormal.

Comment

There is a large body of evidence that placental ischemia is present in women whose pregnancies are complicated by preeclampsia.[12] Previous studies have used nitrous oxide diffusion, injection of radioactive sodium into the intervillous space, and placental clearance of labeled dehydroisoandrosterone to show the reduction of uterine blood flow in preeclamptic pregnancies. These techniques have sources of error and frequently require specialized expertise or the injection of radioactive substances. Although they may be valuable research tools, none of these methods are useful to the clinician.

Physiologic states similar to preeclampsia (primarily hypertension and proteinuria) have been produced in a variety of laboratory animals by reducing uterine blood flow.[12] The techniques are difficult and experimental results are frequently not reproducible. No satisfactory animal model of preeclampsia exists today. Whether the reduction of blood flow to the placenta is the cause or effect of preeclampsia remains an open question.

This study demonstrates that the majority of women with clinically significant hypertensive syndromes in pregnancy have evidence of reduced velocity flow in the uterine or umbilical arteries. Women with decreased uterine but normal umbilical flow frequently were delivered of low birth weight infants, but most often this was the result of prematurity rather than growth retardation. There was no significant increase in abnormal nonstress test results or fetal distress in labor. Their disease probably represents a relatively acute event with increased uterine artery resistance and decreased blood flow. This may be a result of vasospasm, thrombosis, or both. Therapeutic regimens aimed at increasing uterine blood flow may be of particular benefit in improving outcome in these pregnancies.

Women with reduced flow velocity in both vessels, uterine and umbilical, have onset of disease earlier in pregnancy and it usually is more severe. We hypothesize that these women never had trophoblastic invasion of the myometrial segment of the spiral arteries that normally occurs at 14 to 16 weeks.[3] To have significant impact on the poor outcome of these pregnancies, intervention will be needed early in pregnancy. More basic research into the mechanisms of implantation are needed. Improving uterine blood flow will probably be more difficult and have less effect on pregnancy outcome than those in the group with normal umbilical and abnormal uterine artery ratios. These women need intensive maternal and fetal surveillance so that delivery can be timed to optimize outcome.

Women with normal uterine but reduced umbilical flow are the most interesting. Although birth weight and gestational age at delivery were similar to those of the group with normal umbilical and abnormal uterine artery ratios, there was a significant increase in the rates of growth retardation and fetal distress in labor. Even in the presence of normal uterine artery development, the umbilical vascular resistance fails to fall as it does in normal pregnancy. This may represent a failure of angioneogenesis because of a lacking fetal factor or acute vasospasm and thrombosis in the placenta. This is a disease state clinically identifiable as preeclampsia that is associated with poor fetal perfusion of the placenta. Based on this, it seems likely that antihypertensive therapy in these patients may have adverse affects on the fetus.

The outcome of pregnancies in women in the group with normal uterine and umbilical artery ratios is not

different from that of the general population. The fetus receives adequate nutrition. Hypertension has little effect on these pregnancies. A disease that clinically appears to be preeclampsia does occur in these women but it occurs late in pregnancy and tends to be mild. Antihypertensive therapy would seem to be of no value to the fetus but may be useful for control of maternal symptoms. Iatrogenic preterm delivery is seldom warranted in these women.

There have been many classifications based on clinical data developed over the years in an attempt to identify those women and their fetuses who are at risk for morbidity and death. Many of these systems are confusing and none are very accurate. The most commonly used system in this country is that prepared by the Committee on Terminology of the American College of Obstetricians and Gynecologists.[18] There are several problems with all classifications. Blood pressure normally varies throughout pregnancy. The absolute value or the change in blood pressure correlates poorly with outcome. Proteinuria, a frequent finding in chronic renal disease, may have little effect on pregnancy outcome. Edema is a frequent normal finding in pregnant women. Classifying women with hypertension according to vascular patterns identifies women with significant disease better than these clinical classifications.

In summary, this study adds additional evidence that placental ischemia occurs in preeclampsia. The ischemia may be present from either the fetal or maternal side. The severity of disease seems to correlate with the degree of ischemia. Those patients with diminished flow velocity from both the fetal and maternal side have poorer outcomes than the other groups.

Doppler velocimetry is a valuable technique that can separate pregnant women with hypertension into four clinically useful categories. A description of the uterine and umbilical artery systolic/diastolic ratio may be helpful in the clinical evaluation of all pregnant women with hypertension. This should lead to better treatment protocols and improved clinical outcome.

Cocaine use during pregnancy: Adverse perinatal outcome

Scott N. MacGregor, D.O., Louis G. Keith, M.D., Ira J. Chasnoff, M.D., Marvin A. Rosner, M.D., Gay M. Chisum, R.N., Patricia Shaw, R.N., and John P. Minogue, D.Min.

Chicago, Illinois

Cocaine use has increased dramatically in the United States during the past decade. The life-threatening cardiovascular and central nervous system complications of cocaine have been well documented; however, few studies have examined the risks of cocaine use during pregnancy. In this report the perinatal outcome data of 70 women receiving care at the Perinatal Center for Chemical Dependence of Northwestern University, whose pregnancies were complicated by cocaine abuse, were compared with those of matched control subjects. The use of cocaine during pregnancy was associated with lower gestational age at delivery, an increase in preterm labor and delivery, lower birth weights, and delivery of small for gestational age infants. (Am J Obstet Gynecol 1987;157:686-90.)

Key words: Cocaine, drug abuse, perinatal morbidity

Cocaine abuse has increased dramatically in the United States during the past decade. It is now estimated that 30 million Americans have used cocaine at least once and, of these individuals, 5 million are thought to be using the drug regularly.[1] The reported increase in the use of cocaine by the general population has been paralleled by a similar increase in use among pregnant women.[2] At present, no medically or pharmacologically accepted definitions exist by which the terms "use" and "abuse" may be differentiated. However, the highly addictive nature of cocaine suggests that they may be used interchangeably. The ability of cocaine to precipitate life-threatening cardiovascular and central nervous system complications has been documented in several reports[3-5]; however, few studies to date have examined the risks of cocaine use to maternal and fetal health.[2,6,7] In this report, we analyze 70 pregnancies complicated by abuse of cocaine and other addictive substances and compare these patients with matched obstetric patients without a history of substance abuse.

Material and methods

The Perinatal Center for Chemical Dependence at Northwestern University was established to provide intensive care to patients with pregnancies complicated by substance abuse. This comprehensive program, including obstetric, pediatric, psychiatric, and social services, attempts to eliminate or decrease further substance abuse during pregnancy and postpartum.

From January 1983 to September 1986, 74 women who had used cocaine during their pregnancies received prenatal care commencing by the second trimester in the obstetric clinic of the Perinatal Center for Chemical Dependence. All were delivered of their infants at Prentice Women's Hospital and Maternity Center of Northwestern Memorial Hospital.

Four women were excluded from statistical analysis. These included one woman with lupus anticoagulant and nine previous pregnancy losses who had another intrauterine death, one woman with rhesus sensitization who had three in utero transfusions and was delivered before term, another woman with a history of habitual abortion who had a spontaneous first-trimester abortion, and one woman who had an intrauterine death after a gunshot wound to the abdomen that was sustained while she was using cocaine. The remaining 70 women were delivered of viable singleton infants. Twenty-four (34%) had used only cocaine, 20 (29%) cocaine and marijuana, and 22 (31%) cocaine and opiates (with or without marijuana); the remaining four (6%) had used cocaine and a variety of other illicit substances (amphetamines, phencyclidine, barbiturates, LSD, benzodiazepines).

Control patients were selected from the general obstetric population receiving care at the same institution. Matching was performed on the basis of maternal age, parity, socioeconomic class, tobacco use, and medical complications. All control patients were delivered of their infants within 60 days of the index pregnancy. Study and control pregnancies were compared by use of the appropriate t test for parametric data and either the χ^2 or Fisher's exact test for nonparametric data.

Results

Prenatal data. Maternal demographic and prenatal data for study and control populations are summarized in Table I. The two groups were similar for the matching factors and prenatal weight gain. However, significant differences were present for prenatal visits as well as for concomitant ethanol abuse, reflective of polysubstance abuse. The difference in gravidity between the two populations appeared to be due to an increased number of abortions (spontaneous and elective) in the study patients compared with the control women (1.7 ± 1.5 versus 0.7 ± 1.2, respectively, $p < 0.005$). As information was not available to document cocaine use at the time of previous pregnancy losses, this difference could not be attributed to use of cocaine.

Obstetric data. Table II summarizes comparisons of obstetric and perinatal outcomes. The mean gestational age at delivery was lower in the study patients than in the control women and the proportion of pregnancies delivered before term was higher in the cocaine-using patients than in the control women. Both differences are significant, and these differences may explain the fewer prenatal visits noted in the study patients. The mean birth weight was significantly less in the study group and comparison of the incidence of low birth weight infants (<2500 gm) between the two groups revealed a significantly increased proportion in the study population. The study patients also had a significantly greater proportion of infants with birth weights less than the tenth percentile by the birth weight tables of Brenner et al.[8] when compared with the control women, 13 of 70 or 18.6% versus 3 of 70 or 4.3%, respectively. Furthermore, significantly fewer study patients had infants with birth weights greater than the

*Cocaine plus any of the following: opiates, marijuana, barbiturates, amphetamines, phencyclidine, benzodiazepines, and LSD.
†Delivery before 37 weeks' gestation.
‡Birth weight <2500 gm.
§Birth weight less than tenth percentile by birth weight curve of Brenner et al.[8]

ninetieth percentile, two of 70 or 2.9% versus 13 of 70 or 18.6% of the control women. The distribution of birth weights in the control women was similar to the distribution in the general obstetric population at this institution when compared by means of the birth weight tables of Brenner et al. The increased frequencies of abruptio placentae and congenital anomalies in the study group (7.1% versus 1.4% and 5.7% versus 1.4%, respectively) compared with the control women suggested clinical if not statistical significance. The increased incidence of both conditions in the study patients suggests the need for close surveillance for these complications in future pregnancies.

Neonatal data. Mean neonatal Apgar scores at both 1 and 5 minutes were lower in the study infants (Table III). However, no differences were observed in the proportion of Apgar scores <7 at either 1 or 5 minutes. Comparison of umbilical artery pH values showed no significant difference in mean values or in the frequencies of pH values either <7.20 or <7.10. Similarly, there were no differences in the frequencies of either meconium or fetal distress between the two groups.

In an attempt to identify subgroups of the study population with increased morbidity, patients who had used only cocaine were compared with those abusing a variety of addictive substances in addition to cocaine (Table IV). The mean birth weights were lower in the cocaine only group, and the proportions of pregnancies with low birth weight (<2500 gm) and birth weights less than the tenth percentile were higher in this group than in the study population who abused multiple substances; however, these differences were not statistically significant.

Comment

The true extent of cocaine use during pregnancy is difficult to estimate, and the maternal and fetal risks of cocaine use have not yet been well documented. Chasnoff et al.,[2] in a report including 23 cocaine-abusing women, suggested that cocaine use during

pregnancy is associated with an increase in previous spontaneous abortions, abruptio placentae, congenital anomalies, and abnormal Brazelton Neonatal Behavioral Assessment Scale evaluations. In another report of only eight patients, Madden et al.[7] concluded that there was no evident symptomatology in the infants born to cocaine-abusing women and suggested that special management schemes were not needed for these infants. However, examination of their data reveals that two (25%) of these infants were assessed as being small for gestational age and one (12.5%) of the infants was delivered before term.

The cocaine-using pregnant woman and her fetus are at risk for life-threatening cardiovascular and central nervous system complications.[3-5] In addition, they are at risk of other potential hazards that are specific to cocaine use during gestation. Among these are the following: decreased uteroplacental blood flow and uteroplacental insufficiency (acute and chronic), maternal hypertension, stimulation of uterine contractions, and fetal vasoconstriction.[9, 10] Uteroplacental insufficiency is associated with diminished birth weight, intrauterine growth retardation, and fetal intolerance to labor.[11] Indeed, infants of women using cocaine had significantly decreased birth weight and an increased incidence of small for gestational age infants (Table II). Maternal hypertension, especially when associated with alterations in uteroplacental blood flow, may increase the risks of abruptio placentae. Although our data failed to reveal statistically significant differences in the frequencies of abruptio placentae between study and control groups, clinically this difference is alarming. If indeed larger studies in the future confirm an association between cocaine use and abruptio placentae, this association could have a significant impact on maternal and fetal morbidity and mortality. Fetal vascular compromise has been suggested as the cause of congenital anomalies, in particular, limb reduction defects,[12] and while our study failed to reveal a significant difference in the incidence of congenital anomalies between the two groups, larger studies may also be necessary to examine this relationship.

The present study data suggest that cocaine use indeed may adversely affect perinatal outcome. Specifically, the use of cocaine during pregnancy was associated with lower gestational age at delivery, an increase in preterm labor and delivery, lower birth weights, and delivery of small for gestational age infants. At present, these data can only be interpreted as demonstrating an association, rather than a causal relationship, between cocaine use during pregnancy and perinatal morbidity because the fundamental pharmacologic data on the effects of cocaine in human pregnancy are incomplete.

It is important to acknowledge several factors that may have influenced our results. First, the cocaine abuser has a marked tendency to abuse more than one substance.[1] As previously noted, only 34% of the study population used cocaine alone. Our inability to show differences on the basis of patterns of substance abuse (Tables IV) suggests that it may matter little if cocaine is used either alone or with other substances of abuse. Analysis of data relative to pattern of abuse based on trimester use was not possible since random urine toxicology screens were available for only the 38 most recent patients. Patient recall cannot be considered reliable to assess trimester use. In the future, pregnancies will be analyzed by use of urine toxicology screens to evaluate the influence of trimester abuse patterns and therapeutic interventions on perinatal outcome. In the patients that have random screening data, only 33% have eliminated cocaine abuse during pregnancy, which was significantly less than the success of therapeutic interventions when cocaine was not the substance of abuse. Information to reliably assess the quantity of cocaine used by each study patient or the purity of the cocaine was also not available. It is recognized that the latter factor may be highly variable.[1]

Second, tobacco use and poor nutritional intake are recognized as being associated with diminished fetal growth.[13, 14] In this study, however, study and control patients were matched for tobacco use, and although detailed dietary histories were not available, no significant differences in prenatal weight gain were noted between the two groups (Table II).

Third, it is possible that our study population may represent only a select portion of women using cocaine during gestation. If indeed cocaine has an adverse effect on pregnancy outcome, as suggested by these study data, selection of patients with the worst patterns of abuse may influence study findings. However, it is also possible that this group may indeed have a more favorable outcome than those patients with similar cocaine abuse that receive no prenatal care.

Finally, despite this being the largest study of cocaine pregnancies to date, the total number of patients studied is limited. It is perhaps more important that the life-style of the addicted pregnant woman simply is not comparable to that of the nonaddicted pregnant woman for the following reasons: (1) As the addiction worsens, the need to procure larger quantities of the addictive agent and the need for more frequent use overwhelms all other considerations of maternal health and fetal well-being; (2) the financial requirements of a heavy addiction are ruinous regardless of the income status of the addict; (3) behavioral patterns commonly considered unacceptable by society frequently emerge as the addict struggles to support her addiction; (4) disintegration of the premorbid personality is a frequent sequela to the exhaustion of physical, emotional, and financial resources.

In spite of the potential limitations of our data, they suggest that cocaine use is associated with preterm delivery, lower birth weight, and small for gestational age infants. Although preterm delivery accounts for only 6% to 7% of all deliveries, 75% of perinatal morbidity and mortality occurs in preterm infants.[15] It is thus conceivable that widespread cocaine use during pregnancy could become a significant and continuing factor adversely affecting local, regional, and national perinatal statistics.

Because of the well-documented vasoconstrictive properties of cocaine,[10] it is also plausible to suggest that cocaine may have a causal relationship to the increased morbidity observed in our study population. Further research is necessary to investigate the effects of cocaine in pregnancy, in particular, its placental and fetal sympathomimetic actions, and to clarify the precise nature of the effects of cocaine in laboratory and larger population studies.

At present we are implementing a policy of more aggressive antenatal surveillance in our clinics, including ultrasound examinations for assessment of congenital anomalies and fetal growth, serial fetal nonstress testing, umbilical Doppler flow studies, and fetal neurobehavioral evaluation. However, education programs aimed at prevention of the initiation of cocaine use are more desirable. To date, the dangers of cocaine have not been adequately recognized by the general public or their physicians.[16]

Neonatal morphometrics and perinatal outcome: Who is growth retarded?

Robert M. Patterson, M.D., and M. R. Pouliot, R.N.
San Antonio, Texas

To evaluate the relationship between neonatal morphometrics and poor neonatal outcome resulting from fetal malnutrition, we prospectively examined 355 sequential live-born, singleton neonates >35 weeks' gestational age. Birth weight, neonatal ponderal index, and midarm circumference to head circumference ratio were measured. A birth weight, ponderal index, or midarm circumference to head circumference ratio ≤tenth or ≥nintieth percentiles for gestational age was considered abnormal. Poor outcome was defined as operative delivery for fetal distress, 5-minute Apgar score <7, meconium aspiration, polycythemia, or hypoglycemia. Thirty-three (9.3%) neonates had perinatal morbidity. Although morbidity was not increased among neonates that were large by any of the criteria, five (25%) of 20 with low birth weight had poor outcome and 18 (26%) of 70 with low ponderal index or midarm circumference to head circumference ratio suffered morbidity. Of the 33 neonates with morbidity, 18 (54.5%) had low ponderal index or midarm circumference to head circumference ratio, but only five (15.2%) had low birth weight. Therefore, low ponderal index and midarm circumference to head circumference ratio are more sensitive predictors of outcome than is birth weight. As such, ponderal index and midarm circumference to head circumference ratio are more appropriate end points for antenatal diagnostic studies than is birth weight. (AM J OBSTET GYNECOL 1987;157:691-3.)

Key words: Neonatal morphometrics, intrauterine nutrition, perinatal outcome

The relationship between birth weight and perinatal outcome is well described, and classification of neonates as small, appropriate, or large for gestational age is common practice.[1-3] Despite the fact that such classification implies only proximity to a mean weight, small infants are commonly referred to as "growth retarded." If neonates are classified by birth weight for gestational age only, many growth-retarded neonates are nutritionally normal and are at no increased perinatal risk.[4]

Recognizing the heterogeneous pathophysiology of variations in fetal growth, some authors recommend neonatal classification based on nutritional status rather than birth weight.[5-7] Ponderal index and midarm circumference to head circumference ratio should theoretically differentiate the malnourished neonate, who is likely to experience perinatal morbidity and death, from the small, normal neonate.

Knowledge of the neonatal morphometrics most commonly associated with poor perinatal outcome is important to perinatologists. Such insight will enable us to develop antenatal diagnostic tests to identify equivalent fetal characteristics and, hopefully, decrease perinatal morbidity. Assuming that abnormalities in fetal growth often result in poor perinatal outcome, we prospectively studied the value of birth weight percentile, ponderal index, and midarm circumference to head circumference ratio in predicting the occurrence of perinatal morbidity. The method most closely related to outcome should provide the most useful prognostic information and should be the end point of antenatal diagnostic endeavors.

Method

At Medical Center Hospital from August 1 to October 31, 1986, a prospective, random, sequential sample of singleton live-born, normally formed infants delivered after 35 weeks' gestational age was selected for study. Weight and crown-heel length were recorded immediately after birth. Ponderal index was calculated ([weight in gm./(length in cm)^3] × 100). Twenty-four to 36 hours after delivery, each neonate was examined by trained personnel and an occipitofrontal head circumference and Dubowitz score were recorded. Gestational age was established on the basis of obstetric data and confirming Dubowitz. The arm circumference at midhumerus was measured with a tape bilaterally and the two measurements were averaged. Midarm circumference to head circumference ratio was calculated ([midarm circumference to head circumference ratio] × 100). Abnormal birth weight, ponderal index or midarm circumference to head circumference ratio was

Table I. Perinatal outcome among 355 neonates classified by birth weight and nutritional status

Perinatal outcome	*Birth weight percentile*					
	≥Nintieth percentile (n = 49)		*<Nintieth percentile and >tenth percentile (n = 286)*		*≤Tenth percentile (n = 20)*	
	Normal	*Thin*	*Normal*	*Thin*	*Normal*	*Thin*
Good (n = 322)	41	2	220	44	9	6
Poor (n = 33)	5	1	10	12	0	5
p Value	0.33		<0.001		<0.03	

Thin = Low ponderal index or low midarm circumference-to-head circumference ratio.

defined as values ≥nintieth or ≤tenth percentiles for gestational age.[2, 5, 7]

An infant with a normal ponderal index and midarm circumference to head circumference ratio was considered well-nourished, whereas an infant with either a low ponderal index or a low midarm circumference to head circumference ratio was considered thin.

Perinatal morbidity was defined as operative delivery for fetal distress, 5-minute Apgar score <7, meconium aspiration, polycythemia, or hypoglycemia.

Statistical analysis was performed by χ^2 or Fisher's exact test where appropriate. A value of $p \leq 0.05$ was considered significant.

Results

A total of 355 patients were enrolled in the study. The mean gestational age and birth weight were 39.3 ± 1.3 weeks and 3314 ± 454 gm, respectively. The mean ponderal index was 2.56 ± 0.3 and the mean midarm circumference to head circumference ratio was 27.2 ± 3.0. Thirty-three (9.3%) patients had perinatal morbidity. There were no neonatal deaths.

Birthweight, ponderal index, and midarm circumference to head circumference ratio were significantly related to the occurrence of perinatal morbidity. However, morbidity was more strongly related to ponderal index ($p < 0.004$) and midarm circumference to head circumference ratio ($p < 0.001$) than to birth weight ($p < 0.03$). Classification of a neonate as large by any of the three methods was not associated with increased perinatal morbidity ($p > 0.43$). Of 20 patients with low birth weight, five (25%) suffered morbidity. Morbidity occurred in 10 (23%) of 44 neonates with low ponderal index and in 11 (36%) of 31 with low midarm circumference to head circumference ratio.

Twenty patients had low birth weights for gestational age. Eleven (55%) were thin. All five patients who suffered perinatal morbidity in this group were thin. Conversely, in all nine well-nourished but lightweight infants, outcome was good ($p = 0.03$) (Table I).

Birth weight was normal in 286 patients. Twenty-two (7.7%) suffered perinatal morbidity. There were 230 well-nourished neonates, 10 (4.4%) of whom suffered morbidity. In contrast, morbidity occurred in 12 (21.4%) of 56 thin neonates with normal birth weight. Of the 22 patients with perinatal morbidity, 12 (54.6%) were thin (Table I).

The occurrence of perinatal morbidity was not significantly related to nutritional status among the 49 neonates with high birth weights.

Among the 355 patients, 70 (19.7%) were thin. Eighteen (25.7%) of those suffered morbidity. Of the 285 well-nourished neonates, 94.7% had normal outcome. With ponderal index and midarm circumference to head circumference ratio used to evaluate neonatal nutritional status, 18 (54.5%) thin neonates were identified among the 33 with morbidity, whereas only five (15.2%) of the 33 had low birth weight for gestational age (Table I).

Seven neonates had both low ponderal index and low midarm circumference to head circumference ratio. Five (71%) of those suffered morbidity. Only one of the five with morbidity had low birth weight.

Birth weight and nutritional status were normal in 276 neonates, 15 (5%) of whom suffered morbidity. Among 59 thin subjects with normal birth weight, 13 (22%) had morbidity. Poor outcome occurred among five of 11 (46%) thin neonates with low birth weight, but there was no morbidity among the nine who were small but well-nourished (Fig. 1).

Comment

Growth retardation is commonly defined as low birth weight for gestational age. However, many small neonates are normal, and one need only recall a neonate with postmaturity syndrome to realize that fetal malnutrition is often independent of birth weight. Scott and Usher[8] demonstrated that small, clinically well-nourished neonates rarely suffered peripartum asphyxia, whereas those with soft-tissue wasting commonly had poor outcome. In another study, Hill et al.[6] found that, regardless of birth weight, long-term neurologic morbidity was more frequent among patients with soft-tissue wasting at birth.

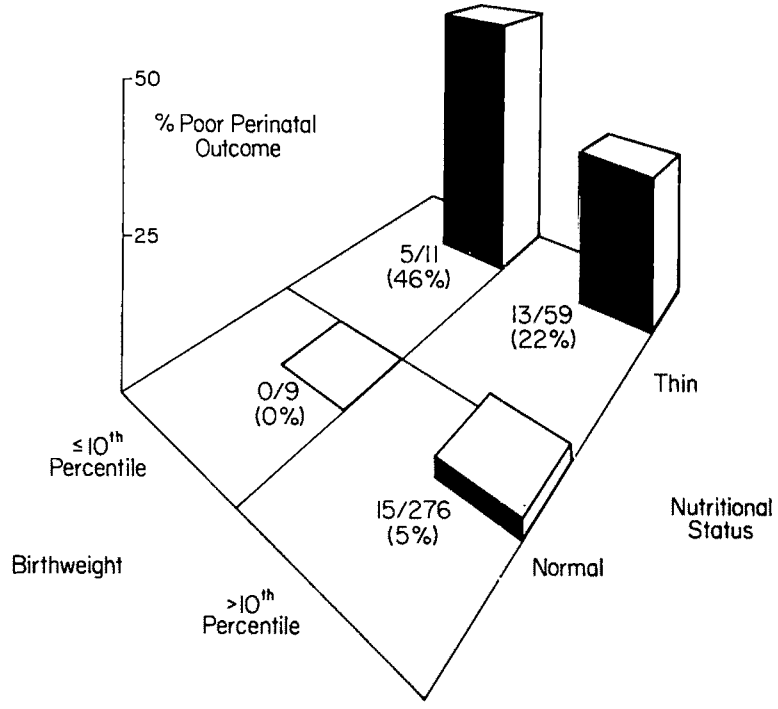

Fig. 1. Outcome among neonates classified by birth weight and nutritional status. Thin = low ponderal index or low midarm circumference to head circumference ratio.

The hypothesis of this study was that nutritional status is more important prognostically than is birth weight. The relationship of birth weight, ponderal index, and midarm circumference to head circumference ratio to perinatal outcome has been documented previously.[1,3-5,7] In this study, classification of each neonate by three different methods allowed for parallel analysis of the relevance of each method. Such an analysis allowed us to identify the method that provided the most useful prognostic information in terms of perinatal morbidity.

The data demonstrate that being small or thin places the fetus and neonate at greater risk for morbidity. Of 20 small neonates, five (23.8%) suffered morbidity. Eighteen of 70 (25.7%) thin neonates had morbidity. However, of the 33 neonates with perinatal morbidity, only five (15.2%) were small, whereas 18 (54.5%) were thin. Therefore, ponderal index and midarm circumference to head circumference ratio were much more sensitive prognosticators than was birth weight.

In conclusion, assessment of nutritional status helps to identify neonates at increased risk for perinatal morbidity, regardless of birth weight. Current methods of surveillance of pregnancies at risk for fetal malnutrition are primarily designed to predict low birth weight.[9] However, these data demonstrate that predicting a thin neonate is more meaningful than predicting birth weight. These findings must be given due consideration in designing antenatal diagnostic studies.

The nonpredictive value of fetal urinary electrolytes: Preliminary report of outcomes and correlations with pathologic diagnosis

Isabelle A. Wilkins, M.D., Usha Chitkara, M.D., Lauren Lynch, M.D., James D. Goldberg, M.D., Karen E. Mehalek, M.D., and Richard L. Berkowitz, M.D.
New York, New York

Fetal urine was sampled 12 times in nine fetuses with sonographically diagnosed urinary tract obstruction to assess renal function. By previously proposed criteria, four fetuses were predicted to have poor renal function. Two of these fetuses were found to have renal dysplasia on autopsy after elective termination. The other two died in the neonatal period but only one of these had histologic evidence of renal dysplasia. Five fetuses were predicted to have good renal function. Three of these developed renal failure after birth, one was found to have renal dysplasia on autopsy after elective termination, and one is alive and well. We conclude that fetal urine electrolytes are not necessarily an accurate predictor of neonatal renal function. (AM J OBSTET GYNECOL 1987;157:694-8.)

Key words: Fetal hydronephrosis, urine electrolytes, fetal renal function

Fetal urinary tract dilatation detected by ultrasonography is a finding associated with a spectrum of prognoses. Mild hydronephrosis in utero may disappear or remain stable, and if it is not progressive it probably has no adverse consequences for the neonate. However, more severe degrees of dilatation can reflect partial or complete urinary tract obstruction that may lead to neonatal renal failure and, if severe oligohydramnios is present, may be associated with pulmonary hypoplasia.

Deciding where a particular case falls in this spectrum is often a challenging task. Clearly, an accurate assessment of renal function and the extent to which it can be expected to deteriorate would be invaluable when candidates are selected for invasive in utero therapy as opposed to expectant management.[1-3] Various predictors of fetal outcome based on ultrasonographic findings or attempts to quantitate urine output in utero have been proposed, but none are entirely reliable. One recently proposed method for evaluating the functional status of an obstructed fetal genitourinary tract is to analyze the fetal urinary electrolytes and osmolarity.[2] The purpose of this study was to prospectively assess these parameters of renal function when managing fetuses with ultrasonic evidence of severe urinary tract obstruction.

Table I. Prognostic criteria for urinary electrolytes

Prognosis	*Sodium (mEq/ml)*	*Chloride (mEq/ml)*	*Osmolarity (mosm)*
Good	<100	<90	<210
Poor	>100	>90	>210

Modified from Golbus et al.[2]

Methods

During a 2-year period, nine patients who have subsequently been delivered were referred to the Mount Sinai Medical Center for consideration of invasive therapy in utero because of an obstructive fetal uropathy. In each case a complete ultrasonographic examination was carried out to characterize the obstruction and rule out associated anomalies. In addition to performing a thorough anatomic survey of the fetus, this examination included a search for renal cysts, hydronephrosis and hydroureters, quantification of bladder size and all loculated collections of urine, and a subjective assessment of amniotic fluid volume. In defining amniotic fluid volume, measurements of individual pockets were not used. Our subjective criteria were as follows: Severe oligohydramnios was present when no amniotic fluid was seen in the uterus. Mild oligohydramnios was present when the volume of fluid was somewhat less than expected for the gestational age. Moderate oligohydramnios included all other cases of decreased fluid. Chromosomal analysis was attempted in all but one case. If the pregnancy was early enough the option of elective termination was given to the parents.

Table II. Urinary electrolytes obtained and predicted results

Patient No.	*Sodium (mEq/ml)*	*Chloride (mEq/ml)*	*Osmolarity (mosm)*	*Predicted function*

In conjunction with the ultrasonographic evaluation, each patient underwent at least one aspirate of fetal urine for analysis. This was performed by sterile technique under direct ultrasound visualization by introducing a 20- or 22-gauge spinal needle into the fetal bladder or dilated renal pelvis. The urine was tested for sodium, potassium, and chloride concentrations and osmolarity. These results were interpreted according to previously published guidelines[2] (Table I) and were used to counsel patients about termination, if appropriate, or further invasive procedures.

Results

Nine fetuses underwent urine sampling. The ultrasonographic findings in each of these cases along with urine values and outcome are listed in Tables II and III. Three pregnancies were terminated electively and the other six were delivered between 29 and 37 weeks.

Antenatally these cases were classified by the diagnosis made from the ultrasonographic findings. Five fetuses had obstruction consistent with a posterior urethral valve or lower tract obstruction. In each case an enlarged bladder was seen, and in four of these cases bilateral hydronephrosis was also observed. Two fetuses had findings suggestive of ureterovesical junction obstruction, unilateral in one case and bilateral in the other. In these two fetuses, bladder size was normal, but hydroureter and hydronephrosis were seen. The remaining two fetuses had ureteropelvic junction obstruction, which was unilateral in one case and bilateral in the other. In these cases isolated hydronephrosis was seen.

Amniotic fluid volume was variable, ranging from severe oligohydramnios to polyhydramnios. Although no fetus with severe oligohydramnios survived, one of these infants who died of pulmonary hypoplasia did not have renal dysplasia detected on autopsy. Otherwise, the volume of amniotic fluid did not correlate with outcome.

Chromosome studies were attempted in eight fetuses, and there was one failed culture. Of the remaining seven fetuses, one had Klinefelter's syndrome (47,XXY) and the others were normal males (46, XY). The fetus with Klinefelter's syndrome also had a ventricular septal defect. No other fetus had any associated anomalies. Chromosomes were obtained from amniotic fluid in four cases, fetal blood in two cases, and fetal urine in two cases.

The electrolytes and osmolarity of all the fetal urinary aspirates are shown in Table II. A second sampling was performed in three fetuses (10, 18, and 57 days after the first), and in each case no significant change was noted in the values in the second specimen.

In four fetuses urinary electrolyte values were consistent with poor renal function. Three of these had ultrasonographic findings of posterior urethral valve and one had unilateral ureteropelvic junction obstruction. The latter fetus (No. 8) had a mildly increased volume of amniotic fluid. In this fetus the urine was aspirated from the dilated renal pelvis. Because the other kidney, bladder, and amniotic fluid volume appeared to be normal, the patient was given a favorable prognosis but elected to terminate the pregnancy. At autopsy, bilateral renal dysplasia was detected.

Only one of the remaining three fetuses with posterior urethral valve and poor electrolytes presented in the second trimester (No. 7). After elective termination the prune belly syndrome with bilateral renal dysplasia was diagnosed at autopsy. The remaining two fetuses (Nos. 1 and 3) were sampled at 27 and 28 weeks' gestation. Although both of these fetuses died shortly after delivery of pulmonary hypoplasia, only one was found to have renal dysplasia at autopsy. The other fetus (No. 3) had histologically normal kidneys with hydronephrosis. No urethral stricture was found. This fetus also had Klinefelter's syndrome and a ventricular septal defect.

In the other five fetuses urinary electrolytes were within the normal range when sampled. Of these, two

*Unilateral.

had a posterior urethral valve, two had ureterovesical junction obstruction, and one had bilateral ureteropelvic junction obstruction. The latter fetus (No. 5) had an elective termination and bilateral renal dysplasia at autopsy.

The two fetuses with posterior urethral valve are the two survivors in this series. In one fetus (No. 4) a vesicoamniotic shunt was placed at 30 weeks' gestation and seemed to malfunction at 33 weeks, at which time the fetus was delivered. This infant is doing well. The other fetus (No. 6) was first evaluated at 18 weeks' gestation. The parents chose not to terminate the pregnancy after having been given a good prognosis after urine sampling at 24 weeks. An attempt was made to place a vesicoamniotic shunt at 32 weeks because of the recent appearance of oligohydramnios, but the attempt failed and the infant was delivered. At the time of the attempted shunt placement, repeat electrolytes were obtained that were unchanged from 8 weeks previously. The neonate had a rising serum creatinine level from birth despite relief of the obstruction. A renal biopsy performed in the neonate revealed a large area of dysplasia. The infant is alive at 7 months of age with moderate renal insufficiency and is awaiting transplant.

One of the two fetuses with ureterovesical obstruction (No. 9) was thought to have unilateral disease on ultrasonographic examination. The other kidney appeared to be normal as did the amniotic fluid volume. The bladder was top normal size. Electrolytes obtained from a bladder aspiration at 31 weeks were normal and the patient was followed expectantly. At 37 weeks' gestation, for the first time, mild oligohydramnios became apparent. After delivery the infant had a rapid downhill course and died at age 7 weeks while on peritoneal dialysis. Autopsy revealed bilateral renal dysplasia, unilateral hydronephrosis, and prune belly syndrome.

The second fetus with ureterovesical obstruction (No. 2) had bilateral disease and was delivered at 31 weeks' gestation after corticosteroid administration. Electrolytes at 28 and 30 weeks' gestation were well within the normal range. The neonate developed progressive renal failure and died at 6 weeks of age. The prune belly syndrome, bilateral renal dysplasia, and a tight urethral stricture were demonstrated at autopsy.

Comment

When urinary tract obstruction is detected in utero, options for management include early delivery, expectant management, and the performance of invasive in utero procedures. Assessment of renal function should be a critical variable in determining which option is appropriate for any given fetus. If renal function is poor, aggressive therapy is not warranted because irreversible damage is likely to have occurred, whereas if good renal function is documented options should be considered that will minimize ongoing damage to the kidneys.

Ultrasonography is the most useful method available for the initial assessment of these disorders. Of primary importance is the differentiation between obstructive and nonobstructive lesions whenever possible. Although this may be suggested by the pattern of dilatation, this distinction cannot always be made.[4, 5] This difference is important because fetuses with nonobstructive lesions are not candidates for shunt placement, and without therapy these neonates usually do very well.

Another vital component of the initial ultrasonographic examination in these patients is the search for associated anomalies. The detection of additional anomalies should disqualify these fetuses from being candidates for invasive therapy.[6] Some controversy ex-

Gestational age when sampled (wk)	*In utero treatment*	*Gestational age at delivery (wk)*	*Predicted function*	*Outcome*
28	Shunt placement	29	Poor	Died age 14 hr; renal dysplasia
28 + 30	None	31	Good	Died age 6 wk; renal failure

17	None	17	Poor	Elective termination; renal dysplasia
22	None	23	Poor	Elective termination; bilateral renal dysplasia
31	None	37	Good	Died age 7 wk; renal failure, severe dysplasia

ists as to the frequency of associated anomalies. Nicolaides et al.[7] described a 23% rate of chromosomal abnormality in their series of 39 fetuses with obstructive uropathy, although this is a higher frequency than is usually quoted. Quinlan et al.[5] found a lower rate of chromosomal abnormalities, only one abnormal karyotype in nine fetuses tested, but 42% had associated anomalies in other systems.

If the ultrasonographic findings are compatible with urinary tract obstruction in the absence of associated anomalies or an underlying chromosomal aneuploidy, a careful selection must be made for candidates for aggressive therapy. Ideal cases are those fetuses at risk for serious renal compromise who have good renal function at the time of diagnosis and no other detectable anomalies.

At this time no completely reliable antepartum method exists for predicting renal function in the neonatal period. Several techniques have been suggested as predictors including assessment of amniotic fluid volume, ultrasonographic evaluation of the renal parenchyma, quantification of upper tract dilation, and analysis of various constituents of fetal urine.[2] Of these, urinary electrolyte and osmolarity analysis has appeared to be the most promising.

Data derived retrospectively from the patients followed by Golbus et al.[2] have suggested that fetuses with isothenuria do poorly, whereas fetuses with dilute urine do well. The cutoff values proposed from this analysis include a sodium level <100 mEq/ml, a chloride level <90 mEq/ml, and an osmolarity value <210 mOsm.

In theory this is an attractive model. It suggests that nonfunctioning kidneys act like a sieve with respect to filtration of serum. On the other hand, functioning kidneys display the normal, selective tubular reabsorption of sodium and chloride. The fetuses in our series were managed prospectively according to these proposed criteria to judge degree of renal impairment in utero. Because the urine sampled in most cases was from the bladder, which is stagnant, this may not accurately reflect the urine that is simultaneously being excreted by the kidney.

In this series, although there were no survivors among the four fetuses with poor predicted function, one had no evidence of renal disease at autopsy. However, the other three were documented to have dysplastic kidneys.

On the other hand, urinary values below the abnormal cutoffs did not reliably exclude the finding of dysplasia or evidence of severe renal dysfunction during the neonatal period. All fetuses with normal values had minimal degrees of oligohydramnios or normal amniotic fluid volumes and the two surviving infants in this series are in this group.

In the neonate, as in the fetus, it may be difficult to assess renal function. Because the serum creatinine level does not begin to rise until after birth, for the first few weeks of life it may not be possible to use this index. Similarly, although urine output can be measured directly, this may be misleading because of postobstructive diuresis in cases in which the sites of obstruction have been bypassed or because of concomitant problems of prematurity or incomplete relief of obstruction. In these situations urinary electrolytes, particularly sodium values, have been suggested as markers of renal function but have been unreliable.[8]

Although our results are seemingly at variance with the findings of Golbus et al.,[2] we have used this information to predict function at a future date, something he did not propose. It may be argued that these urinary parameters are only a reflection of the current status

of the fetus and that a delay in delivery invalidated their use in these cases. However, in those cases in which predicted function via electrolyte analysis did not correlate with outcome at delivery, a delay in delivery alone was not an adequate explanation for the discrepancy.

In patients 2, 5, and 6, <1 week passed between the final fetal urine analysis and delivery. A 5-week delay in delivery followed sampling in patient 3; however, because the values were predictive of dysplasia and it did not exist at 32 weeks, it could not have been present at 27 weeks. Finally, in patient 9 there was a 6-week delay from urinary sampling to delivery. The postmortem histologic findings of severe dysplasia imply an early profound insult that is not the result of progressive disease in the third trimester. Finally, even if this test is only predictive of current renal status, this will weaken its value as an indicator of neonatal outcome and thus its value as an adjuvant to counseling patients with a fetus with obstruction.

In this group of patients three different outcome variables have been used: neonatal renal function, death, and pathologic diagnosis. Although neonatal renal function was our ultimate concern, it was not measurable in three electively terminated fetuses or two neonates who died shortly after birth. Using death alone as an outcome parameter is problematic because other nonrenal causes of neonatal death such as pulmonary hypoplasia are included, whereas neonates who survive with renal impairment are not. In addition, electively terminated fetuses could not be included in such an analysis. Thus the pathologic diagnosis of dysplasia is an important end point. In all cases of dysplasia found at autopsy the damage was so severe and extensive that, in the opinion of our pathologists, it was not compatible with normal renal function.

There remain many unanswered questions in the prenatal management of fetal urinary tract obstruction. First, there is controversy about whether relieving severe obstruction is useful when this is present early in gestation. Seeds and Mandell[9] have suggested that intervention may not be indicated in these cases because renal damage is uniformly too advanced, but this has been disputed by Manning et al.[10] Conversely, when good renal function is present in the third trimester, it may be unlikely that relief of obstruction offers any advantage over expectant management and early delivery.[4, 11]

Finally, in all of these cases renal failure in the child who is apparently normal at birth may develop during the first few years of life. Thus, long-term follow-up of reported cases must also be sought to fully evaluate the success of intervention.

In conclusion, although assessment of fetal renal status in cases of obstructive uropathy in utero is of great potential value, this study suggests that assessment of fetal urinary electrolytes and osmolarity is not an optimal way to accomplish this goal. In four cases in which the values suggested poor function the outcome was universally dismal, but one of these fetuses did not have evidence of dysplasia at autopsy. On the other hand, in five cases in which fetal urinary studies predicted good renal function, a wide spectrum of findings were observed in the neonates.

Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short- and long-term metabolic control in gestational diabetes

Lois Brustman, M.D., Oded Langer, M.D., Samuel Engel, M.D., Akolisa Anyaegbunam, M.D., and Roger Mazze, Ph.D.

Bronx, New York

Glycosylated hemoglobin and glycosylated serum protein have been suggested as tools for evaluation of long- and short-term glycemic control, respectively. Twenty-six patients with gestational diabetes were prospectively studied to determine the relationship of glycosylated hemoglobin and glycosylated serum protein to metabolic control. To verify the accuracy of blood glucose data, a memory-based reflectance meter was used for subjects with gestational diabetes who tested 6.5 ± 1 times per day. Our analysis revealed that despite a statistically positive correlation between glycosylated hemoglobin, glycosylated serum protein, and verified data, their use as a clinical tool is limited because of their poor predictability. (Am J Obstet Gynecol 1987;157:699-703.)

Key words: HbA_1, glycosylated serum protein, verified blood glucose data

The association between the level of metabolic control and perinatal complication of diabetes in pregnancy is well established.[1,2] Therefore, methods to evaluate glycemic control in these patients have been a subject of research during the past several years. It has been suggested that glycosylated hemoglobin (HbA_1) and glycosylated serum protein are useful as clinical tools in assessing long- and short-term glycemic control, respectively.[3,4] Several investigators have found that the level of HbA_1 in pregnant patients is directly related to blood glucose values and reflects glucose control for the previous 4 to 12 weeks (long-term control), paralleling the life span of the red blood cell.[5-7] In contrast, glycosylated serum protein was found to be a predictor of short-term glycemic control (1 to 2 weeks).[3] Our study set out to determine the relationship between HbA_1, glycosylated serum protein, and verified self-monitored blood glucose.

Method and material

A prospective study involving 26 gestational diabetic and 18 nondiabetic women was performed. Subjects with hemoglobinopathies, renal failure, and a history of drug abuse were excluded. Gestational diabetes was diagnosed pursuant to the National Diabetic Data Group criteria.[8] Obesity was measured by body mass index (kilograms/height^2), using prepregnancy weight. From the time of diagnosis of gestational diabetes, patients were given a memory-based reflectance meter assuring reliable documentation of blood glucose data.[9] Capillary blood glucose was to be tested seven times a day, which included fasting, preprandial, 2-hour postprandial, and bedtime values from the time of diagnosis to delivery. Patients were instructed in the use of the memory-based reflectance meter and tested for their skills at entry to the study and each subsequent visit. Patients were seen at two-week intervals. During each clinic visit blood samples for HbA_1 and glycosylated serum protein were drawn. All samples were obtained and analyzed during the same day in the General Clinical Research Center Laboratory. HbA_1 was measured by a microcolumn cation exchange method with the normal range defined as between 5% and 7%. Glycosylated serum protein was evaluated with the Δ Glyc-Affin Glycosylated Serum Protein assay in which glycosylated serum protein was separated by a chromatographic column and then its total percent calculated by a spectrometer evaluation at 595 mm. Normal values of glycosylated serum protein were established at 8% to 12.9%.

For the controls, one HbA_1 and glycosylated serum protein determination after a normal glucose tolerance

test result was performed to establish the normal range for both assays in pregnancy. For subjects with gestational diabetes, analysis was performed to evaluate HbA_1 and glycosylated serum protein with respect to blood glucose data for five periods: period 1, weeks 1 and 2; period 2, weeks 3 and 4; period 3, weeks 5 and 6; period 4, weeks 7 and 8; and period 5, weeks 9 and 10. Additional analysis was performed on blood glucose data cumulative for 4, 6, 8, and 10 weeks compared with HbA_1 measured to coincide with these periods.

Determination of normal ranges for both glycosylated serum protein and HbA_1 were calculated with the control subjects' data. For the purpose of analysis, before the study, 100 mg/dl was selected as the cutoff value for the upper limits of normal for overall mean blood glucose values for any 2-week period. Univariate and bivariate statistical analysis was performed. For categoric data χ^2 and Fisher's exact tests were used and for continuous data the Student t test was used. The association between HbA_1 and glycosylated serum protein and glucose data was measured by Pearson's correlation coefficient.

Results

Twenty-six women with gestational diabetes and 18 nondiabetic women participated in the study. A comparison of the two groups showed no significant difference for maternal age, gestational age at delivery, parity, and maternal weight. A significant difference was found in the incidence of obesity at entry into the study, with the group with gestational diabetes having almost a threefold higher rate (Table I). Evaluation of self-monitored blood glucose testing for the group with gestational diabetes revealed an average of 6.5 ± 1 per day.

In period 1 the association between HbA_1, glycosylated serum protein, and glucose level was measured. As shown in Table II, there was no relationship when the mean fasting blood glucose level (by self-monitored

blood glucose) was associated with either glycosylated serum protein or HbA_1. A significant correlation was uncovered for the relationship between preprandial blood glucose values and glycosylated serum protein, as well as HbA_1. The 2-hour postprandial values were also significantly correlated with the glycosylated serum protein and HbA_1 for the period.

We repeated the analysis of the relationship between HbA_1 and glycosylated serum protein and verified blood glucose data for periods 2 through 5. The level of metabolic control throughout pregnancy as gauged by self-monitored blood glucose values for each study subject with gestational diabetes remained stable, resulting in an overall mean of 92 ± 28 mg/dl. A significant positive correlation was found between HbA_1, fasting, preprandial, postprandial, and overall mean values. In Table III we summarize the data for period 5 (which was virtually the same as that for the previous periods). During this period, capillary blood glucose values and glycosylated serum protein values were determined for 18 subjects with an overall correlation of $r = 0.52$ ($p < 0.05$). For the same period a correlation coefficient of $r = 0.51$ ($p < 0.001$) was calculated for HbA_1. The difference in level of significance was the result of the unequal number of study subjects.

Fig. 1 shows that for all subjects both the mean glycosylated serum protein and the mean HbA_1 levels remained stable throughout the study period. Greater variability at each period was found for the glycosylated serum protein values compared with the parallel HbA_1 values.

We next examined the relationship between HbA_1 and capillary blood glucose values for cumulative periods of 4, 6, and 8 weeks, respectively. We found a similar level of predictability for all time intervals as that calculated for 2 weeks ($r = 0.51$ to 0.62). Examination of glycosylated serum protein in relationship to glucose level at any 1- or 2-week consecutive interval after period 1 demonstrated a significant correlation at all points of glucose determination during the day ($r = 0.47$ to 0.69).

Finally, the distribution of HbA_1 and glycosylated serum protein in relation to mean blood glucose levels and metabolic control was considered. Illustrated in Fig. 2 is the scattergram of the mean HbA_1 versus mean blood glucose value for each patient for the five periods. Fig. 2 shows that 83 of the 117 points fall within the lower left quadrant bordered by the upper limits of normal HbA_1 and mean blood glucose values (based on the control values). Thus 71% of the time there was consistency between HbA_1 and mean blood glucose values, both simultaneously falling within the normal range. In Fig. 3 the same analysis is used to show that 39 of the 89 points fall within the limits of the normal range for glycosylated serum protein and mean blood glucose values (based on the control values). We therefore found that 43% of the time the mean blood glucose and mean glycosylated serum protein values coincided.

Comment

Traditionally HbA_1 has been considered a predictor of long-term glycemic control.[10] The rationale for this assumption is that HbA_1 is dependent on the life span of the red blood cell, which averages 120 days.[5,6] However, it has been reported that the representative time span for the predictability of HbA_1 ranges from 4 to

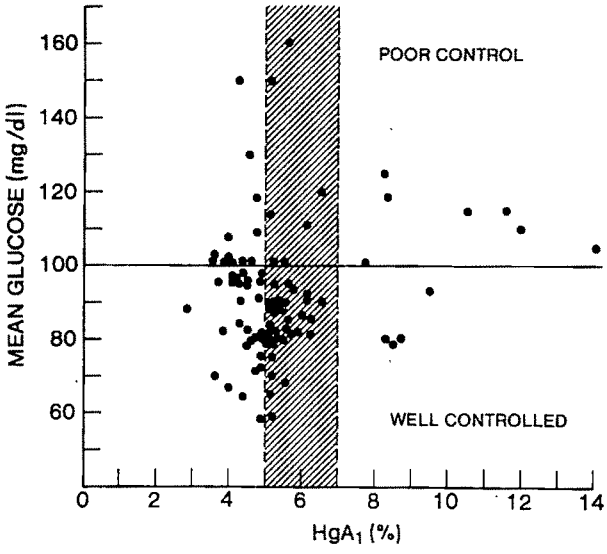

Fig. 2. Distribution of HbA_1 results in relationship to mean blood glucose levels.

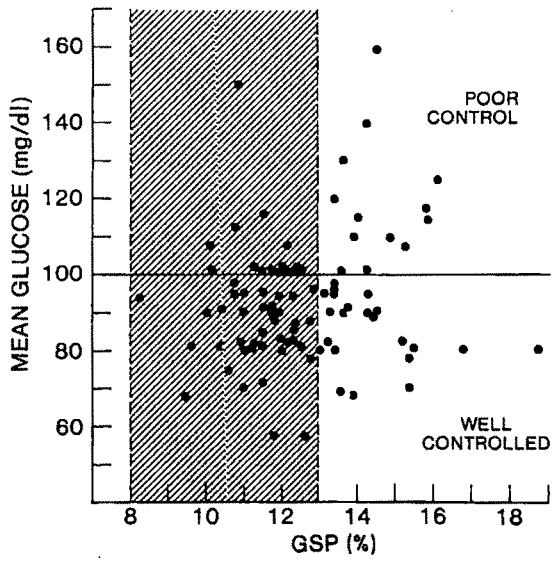

Fig. 3. Distribution of glycosylated serum protein *(GSP)* results in relationship to mean blood glucose levels.

12 weeks.[11-13] To date, the question of what is the best representative time interval for HbA_1 as a predictor of long-term control has not been fully answered. Our study attempted to answer this question by examining the relationship between HbA_1 and glycemic control at 2-, 4-, 6-, and 8-week intervals throughout pregnancy complicated by gestational diabetes. We found that the predictive value of HbA_1 did not improve when the length of time covered with the assay was extended by 2, 4, and 6 weeks. Thus the use of HbA_1 as a long-term predictor must be questioned.

Glycosylated serum protein is traditionally recognized as an evaluator of short-term glycemic control.[3, 4] This has not been studied extensively during pregnancy. Only two studies have examined the role of glycosylated serum protein in gestational diabetes. The first addressed the role of glycosylated serum protein as a diagnostic tool for gestational diabetes.[14] In this study, glycosylated serum protein was found to have a poor correlation to the oral glucose tolerance test. The second study investigated the association between glycosylated serum protein and metabolic control. However, the duration of time, level of control, and method used to obtain glucose data were not specified.[15] The results of the latter study revealed that glycosylated serum protein values were not consistently elevated in patients with gestational diabetes. In our study a predictability of approximately 25% was found for all intervals throughout the study period. Furthermore, there was a high percentage of false positive and false negative test results in relationship to mean glucose values (as was found in HbA_1). Thus a question must be raised as to the clinical usefulness of glycosylated serum protein for verification of metabolic control.

It is our contention that with the use of a memory-based reflectance meter to assure reliable glucose data, we were able to study the true relationships in gestational diabetes of HbA_1 and glycosylated serum protein to metabolic control in a longitudinal manner. This led us to conclude that despite a statistically positive correlation between HbA_1 and mean blood glucose levels, and between glycosylated serum protein and mean blood glucose levels, their use as a clinical tool is limited because of poor predictability.

Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term

Clifford J. Bochner, M.D., Arnold L. Medearis, M.D., John Williams III, M.D., Lony Castro, M.D., Calvin J. Hobel, M.D., and Maclyn E. Wade, M.D.
Los Angeles, California

The purpose of this study was to determine whether an early third-trimester fetal abdominal circumference measurement can be used in patients with gestational diabetes to predict the presence or absence of macrosomia and labor dystocia at term. The predictive accuracy of a 30- to 33-week abdominal circumference measurement was tested, using the ninetieth percentile as the discriminant point. The study consisted of 201 patients with gestational diabetes who maintained weekly fasting glucose levels <100 mg/dl and 2-hour postprandial glucose levels <120 mg/dl with dietary management alone. The predictive accuracy of a 30- to 33-week fetal abdominal circumference measurement was 96.4% for ruling out macrosomia and 56.3% for predicting macrosomia. Patients with fetal abdominal circumference measurements >the ninetieth percentile at 30 to 33 weeks had a significantly increased incidence of cesarean section for failure to progress, shoulder dystocia, and birth trauma, whereas patients with abdominal circumference measurements ≤the ninetieth percentile were at no greater risk than the general population. These results suggest that patients with non-insulin-dependent gestational diabetes with fetal abdominal circumference measurements ≤the ninetieth percentile at 30 to 33 weeks are not at increased risk for macrosomia, cesarean section, or birth trauma at term, as long as their weekly glucose testing remains within normal limits. Efforts to decrease the incidence of macrosomia and its attendant risks should focus on those gestational diabetic patients whose fetal abdominal circumference >the ninetieth percentile at 30 to 33 weeks. (Am J Obstet Gynecol 1987;157:703-8.)

Key words: Gestational diabetes, macrosomia, ultrasound screening

Gestational diabetes is associated with a significantly increased incidence of fetal macrosomia[1-3] and its attendant risks, including traumatic delivery, shoulder dystocia, and cesarean section. In an attempt to decrease the incidence of gestational diabetes–related morbidity, recent studies have investigated the use of either prophylactic insulin[4] or intensive maternal home glucose monitoring[5] for all patients with gestational diabetes. These studies have reported a significantly decreased incidence of macrosomia and labor morbidity. However, it is not certain whether the logistic constraints of having all patients with gestational diabetes on these ancillary therapies does not outweigh the benefits, particularly because the majority of gestational diabetics treated with dietary control alone and weekly glucose surveillance do not have infants with macrosomia.

Given the potential benefits, as well as the considerable logistic constraints, it would be extremely ben-

eficial if we could identify those patients who might benefit from ancillary treatment and those for whom it is unnecessary. Therefore the purpose of this study was to determine whether early third-trimester ultrasonographic assessment of the fetal abdominal size can be used as a screening tool to identify which patients with gestational diabetes may potentially benefit from additional therapies.

Material and methods

The study group consisted of 201 patients with gestational diabetes followed at the Cedars-Sinai antepartum testing unit between January 1984 and October 1986. Gestational diabetes was diagnosed according to the criteria of O'Sullivan and Mahan,[6] modified to correct for the methodologic change from the Somogyi-Nelson method to glucose oxidase and for measurement of plasma rather than whole blood glucose.[7] With a 100 gm glucose tolerance test, gestational diabetes was diagnosed if two or more of the following criteria were met or exceeded: fasting, 95 mg/dl; 1 hour, 180 mg/dl; 2 hours, 155 mg/dl; and 3 hours, 140 mg/dl.

Patients were managed with a diabetic pregnancy diet (30 to 35 kcal/kg of ideal body weight and consisting of 25% fat, 25% protein, and 50% complex carbohydrate) and weekly fasting and 2-hour postprandial plasma glucose measurements. To be included in the study, gestational diabetes had to be diagnosed before 34 weeks' gestational age, and the weekly fasting and 2-hour postprandial plasma glucose values had to be maintained at <100 mg/dl and 120 mg/dl, respectively, on diabetic diet alone. In addition, patients had to have accurate early pregnancy dating criteria (accurate date of last menstrual period and ultrasonographic examination performed in the first or second trimester) and they had to have delivered beyond 36 completed weeks of gestational age.

All study patients underwent ultrasonographic fetal measurements between 30 and 33 completed weeks of gestational age, with an ATL linear-array real-time ultrasound scanner, model 4000 (Advanced Technology Laboratories, Seattle, Washington). The techniques used for abdominal circumference measurement and calculation were the same as those reported by Shields et al.[8] The accuracy of a 30- to 33-week fetal abdominal circumference measurement for predicting the presence or absence of fetal macrosomia, labor dystocia, shoulder dystocia, or birth trauma at term was tested using the nintieth percentile as the discriminant point.

Abdominal circumference percentile ranks were assigned according to the previously established reference growth curves for the Cedars-Sinai population. The general formula used for the predicted abdominal circumference at each gestational age was: abdominal circumference = $-12.67 + 1.59$ (gestational age) $- 0.0102$ (gestational age)^2 ($R^2 = 0.945$, SE of the estimate = 1.828). The individual confidence interval for the ninetieth percentile was calculated according to the following formula: ninetieth percentile = predicted abdominal circumference + 1.282 × square root (1 + 1/347 + [gestational age − 29.08]^2/18723) × 1.889. The abdominal circumference values representing the ninetieth percentile were 28.3, 29.3, 30.2, and 31.1 cm, respectively, for 30, 31, 32, and 33 weeks' gestation.

Macrosomia was considered to be a birth weight >the ninetieth percentile for the Cedars-Sinai patient population. The standard reference curves for our population were developed by a regression analysis of the birth weights from 10,135 singleton pregnancies that included all deliveries of normal live-born neonates for the years 1983 and 1984. The regression analysis was stratified and the best fit achieved by use of an inflection point of 35.0 weeks, selected to give the least SE of the estimate.

The labor and delivery and neonatal records were reviewed for each patient in the study. Delivery outcomes were compared between patients with fetal abdominal circumferences ≤the ninetieth percentile at 30 to 33 weeks' gestational age and those with abdominal circumferences >the ninetieth percentile. Labor dystocia was defined as failure to progress in labor for >2 hours, despite adequate contractions, once the active phase of labor had begun (cervical dilatation >3 to 4 cm). Shoulder dystocia was considered to be present if fetal shoulder impaction at delivery required additional maneuvers other than head traction. Birth trauma included fetal fractures, hematomas, and soft tissue injuries.

Statistical analyses were performed by χ^2, Fisher's exact test, or the unpaired t test, as appropriate. A p value <0.05 was considered significant.

Results

In the overall study population of 201 patients, infants with a birth weight >the ninetieth percentile had significantly increased incidences ($p < 0.001$) of cesarean section for failure to progress in labor (41.7% versus 14.3%), shoulder dystocia (16.7% versus 0.7%), and birth trauma (3.6% versus 20.8%), compared with infants with a birth weight ≤the ninetieth percentile. Of the 31 infants with a birth weight >4000 gm, 20 received a trial of labor, and this resulted in eight cesarean sections for failure to progress, four cases of shoulder dystocia, and five infants with birth trauma.

When the study patients were grouped according to fetal abdominal circumference measurements at 30 to 33 weeks' gestational age, there were no significant differences between the groups in terms of the mean maternal age, percentage of nulliparous women, mean prepregnancy weight, mean gestational age that dia-

betes was diagnosed, or the timing of the screening fetal abdominal circumference measurement (Table I). However, at term the group that had a fetal abdominal circumference >the ninetieth percentile between 30 and 33 weeks had a significantly higher ($p < 0.001$) mean birth weight, percentage of infants with birth weight >the ninetieth percentile, and percentage of infants weighing >4000 gm (Table II).

The accuracy of a 30- to 33-week fetal abdominal circumference for predicting the presence or absence of macrosomia at term (using the ninetieth percentile as the discriminant point) is presented in Table III. The positive predictive value of an abdominal circumference >the ninetieth percentile for predicting a fetal birth weight >the ninetieth percentile was only 56.3%, and for predicting a birth weight >4000 gm it was only 40.6%. Conversely, the negative predictive value of an abdominal circumference ≤the ninetieth percentile for predicting the absence of macrosomia was 96.4%. The sensitivity of a fetal abdominal circumference >the ninetieth percentile for identifying those patients with eventual macrosomia was 87.8%, whereas the specificity of a fetal abdominal circumference ≤the ninetieth percentile for identifying those patients without macrosomia was 82.5%.

Only one elective cesarean was performed for presumed fetal macrosomia. Of the 164 patients who underwent a trial of labor, the group with fetal abdominal circumferences >the ninetieth percentile between 30 and 33 weeks did not have an overall significantly increased incidence of cesarean section for failure to progress, compared with patients with abdominal circumferences ≤the ninetieth percentile (Fig. 1). However, patients with fetal abdominal circumferences >the ninetieth percentile did have a significantly increased incidence of cesarean section for failure to progress ($p < 0.001$) beyond 39 completed weeks' gestational age. Overall, they also had significantly increased incidences of shoulder dystocia and birth trauma ($p < 0.001$) compared with patients with fetal abdominal circumferences ≤the ninetieth percentile (Fig. 2). When compared with the general Cedars-Sinai

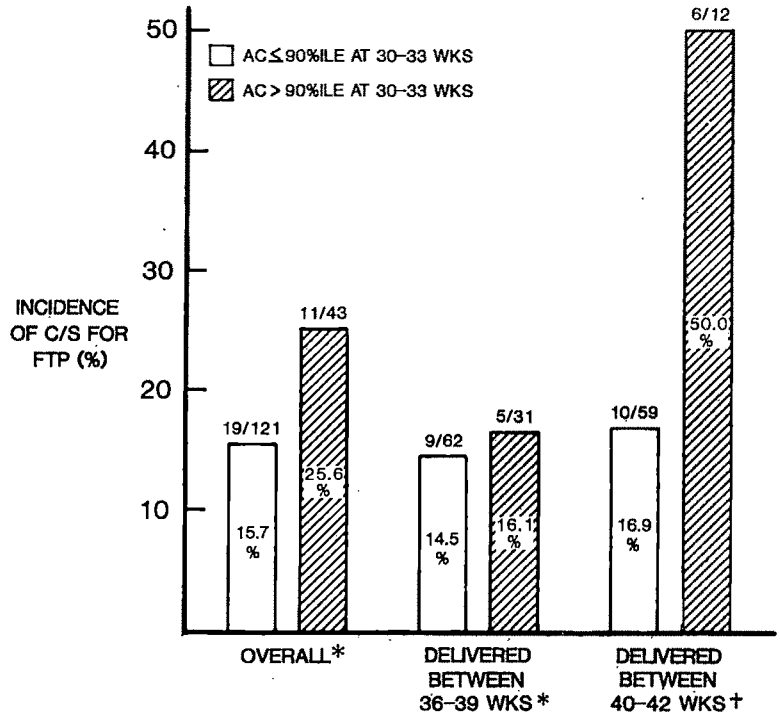

Fig. 1. The incidence of cesarean section for failure to progress in patients given a trial of labor. *not significant; †$p < 0.001$; *AC*, abdominal circumference; *C/S*, cesarean section; *FTP*, failure to progress.

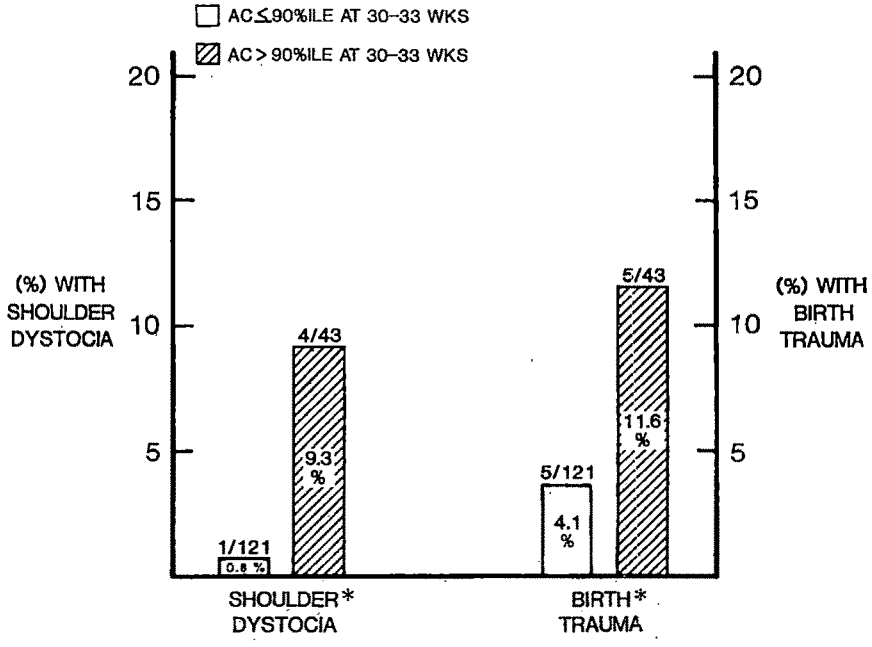

Fig. 2. The incidence of shoulder dystocia and birth trauma in patients given a trial of labor. *$p < 0.001$; *AC*, abdominal circumference.

term population, the group with fetal abdominal circumferences ≤the ninetieth percentile was not at increased risk for cesarean section as a result of failure to progress (15.7% versus 16.6%) or shoulder dystocia (0.8% vs 0.8%).

Comment

Gestational diabetes has been shown to result in a significantly increased incidence of fetal macrosomia and its associated risks, including labor dystocia and trauma.[1-5] Although recent investigators have shown a

decrease in macrosomia-related morbidity, by either treating all gestational diabetics with prophylactic insulin[4] or increasing glucose surveillance,[5] the majority of gestational diabetics do not suffer from macrosomia-related morbidity when managed simply with dietary control and weekly glucose testing alone. This study, therefore, was undertaken in an attempt to determine whether early third-trimester screening can identify which patients may potentially benefit from ancillary therapy.

Previous investigators have attempted, at term, to use ultrasonographic parameters of fetal size to identify patients with fetal macrosomia,[9-11] as well as those at risk for shoulder dystocia.[12] Others have studied diabetic patients during the preterm period in an attempt to predict which ones are destined to become macrosomic at term.[13, 14] We chose a gestational age of 30 to 33 weeks as our screening time period because a study by Ogata et al.[13] showed that in diabetic patients with eventual macrosomia at term, the fetal abdomen initially began to demonstrate accelerated growth between 28 and 32 weeks' gestational age. In addition, this is a time period that is considered to be early enough in pregnancy for insulin therapy to be beneficial, if needed.[4]

The fetal abdominal circumference was chosen as the screening parameter because it has been shown to be the single most accurate fetal growth parameter for predicting macrosomia in patients with accurate dating.[11, 13] This is likely because the fetal abdomen is the body part most affected by diabetes-induced accelerated growth.[13] The ninetieth percentile was chosen because it has been shown to be the best abdominal circumference percentile value to use for predicting macrosomia.[11, 13]

Our data agreed with these findings. The fetal abdominal circumference in this study had better predictive values for the presence or absence of macrosomia at term compared with the other individual fetal structural parameters measured including biparietal diameter, head circumference, and femur length, or the calculated estimated fetal weight,[15] head circumference/abdominal circumference ratio, or femur length/abdominal circumference ratio. However, the predictive value for fetal macrosomia was not statistically improved by combining an estimated fetal weight >the ninetieth percentile with an abdominal circumference >the ninetieth percentile, in contrast to the findings of Tamura et al.[17] This may be because their values were obtained closer to term, at which time the progressive accelerated fetal growth may have resulted in both the fetal abdominal circumference and biparietal measurements reaching higher percentile ranks.

The abdominal circumference ninetieth percentiles calculated for our population between 30 and 33 weeks are virtually the same as those of Deter et al.[16] In addition, the birth weight ninetieth percentiles at term were within 20 to 30 gm of the overall California birth weight curves.[17] Therefore these tables can be used interchangeably with ours for the purposes of this study. However, we agree in principle with Deter et al. that to optimally evaluate specific populations, individual growth and birth weight curves should be determined.

The study results suggest that an ultrasonic fetal abdominal circumference measurement ≤the ninetieth percentile between 30 and 33 weeks' gestation is a highly accurate predictor for the absence of either fetal macrosomia (Table III), dystocia, or birth trauma (Figs. 1 and 2) at term. It appears that if the influence of gestational diabetes has not resulted in accelerated fetal growth by 30 to 33 weeks, it is unlikely that patients with normal weekly glucose testing will develop macrosomia and they can be treated with dietary management alone.

Conversely, a fetal abdominal circumference >the ninetieth percentile between 30 and 33 weeks' gestation was not an accurate predictor of macrosomia at term (Table III). Therefore we cannot reliably predict the delivery outcome in such patients. However, an abdominal circumference >the ninetieth percentile did have a high sensitivity for identifying patients with eventual macrosomia (Table III), and it was associated with a significantly increased incidence of labor dystocia, shoulder dystocia, and birth trauma (Figs. 1 and 2).

If ancillary therapies are to be employed, patients with a fetal abdominal circumference >the ninetieth percentile at 30 to 33 weeks appear to be the ones who may benefit. These patients may also benefit from induction of labor before 40 weeks' gestational age, because the risk for failure to progress in labor did not statistically increase until that point. Focusing our efforts on those patients with gestational diabetes with a fetal abdominal circumference >the ninetieth percentile at 30 to 33 weeks may enable us to decrease the incidence of gestational diabetes–related macrosomia and morbidity while minimizing the inconvenience to the overall population with gestational diabetes and the logistic constraints to the medical care system.

Chorionic villus sampling is associated with normal fetal growth

John Williams III, M.D., Arnold L. Medearis, M.D., Moraye B. Bear, M.A., and Michael M. Kaback, M.D.

Los Angeles and Torrance, California

Seventy-eight singleton term neonates, delivered of women who were 35 years of age or older after chorionic villus sampling at 9 to 11 weeks' gestation, were compared with 1335 singleton control neonates delivered at term of mothers 35 years of age or older before the clinical application of chorionic villus sampling at our institution. No statistically significant differences were found in birth weight, crown-heel length, or ponderal index between control neonates and neonates delivered after chorionic villus sampling. The sample sizes necessary to detect a 5% difference in population means at an alpha error level of 0.05 and beta error level of 0.1 were calculated for the measured variables and achieved before analysis. This study suggests that patients undergoing chorionic villus sampling are not at increased risk for the development of decreased fetal growth or intrauterine growth retardation. (AM J OBSTET GYNECOL 1987;157:708-12.)

Key words: Chorionic villus sampling, intrauterine growth retardation, fetal growth

Decreased fetal growth and intrauterine growth retardation are theoretical risks of chorionic villus sampling. The U.S. Food and Drug Administration has required patients undergoing chorionic villus sampling to be counseled of this risk. Early reports suggested that the percentage of infants delivered after chorionic villus sampling with birth weights below the tenth percentile is no different from that in the general population.[1,2] However, comparisons of weight, length, and proportionality between neonates delivered after first-trimester chorionic villus sampling and a suitable control population have not been reported. The purpose of this study was to investigate the effect of chorionic villus sampling on fetal growth as assessed by the neonatal evaluation of birth weight, crown-heel length, and ponderal index in the term pregnancy to determine whether a decrease in size or distribution of these obstetric outcome variables could be shown.

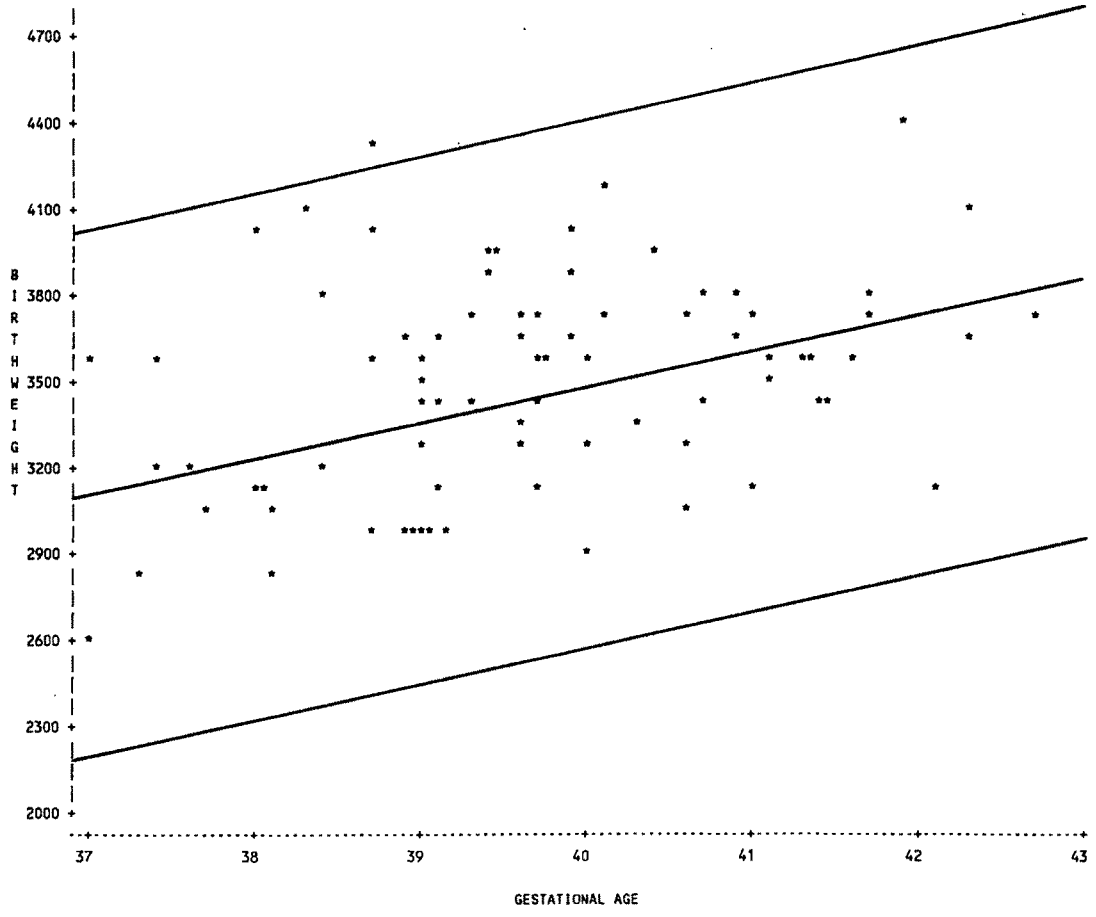

Fig. 1. The distribution of neonatal birth weight (measured in grams) versus gestational age from pregnancies having had chorionic villi sampling at 9 to 11 weeks' gestation. Predicted mean, ninety-fifth and fifth percentiles for the control population are superimposed on the graph.

Table I. Variables studied in the control and chorionic villi sampling populations

	Controls	*Chorionic villi sampling*	*p Value*
No.	1335	78	—
Gestational age (wk) (mean ± SD)	39.8 ± 1.3	39.7 ± 1.4	0.33*
Maternal age	36.9 ± 1.93	36.9 ± 2.59	0.78*
Parity	1.18 ± 1.39	1.14 ± 1.02	0.78*
Birth weight (gm)	3458 ± 494	3503 ± 380	0.31*
Crown-heel length (cm)	51.8 ± 2.6	51.7 ± 2.0	0.49*
Ponderal index	2.48 ± 0.29	2.54 ± 0.27	0.07*

*Not statistically significant.

Material and methods

Seventy-eight term (36 to 42 completed gestational weeks) neonates delivered of patients who had undergone transcervical chorionic villus sampling at 9 to 11 weeks' menstrual age were evaluated at delivery for birth weight and crown-heel length. The ponderal index (birth weight/[crown-heel length]^3 · 100) was calculated. All infants were products of singleton pregnancies and had normal karyotypes. The maternal age at delivery was between 35 and 45 years. Aspiration of chorionic villi was performed with a 16-gauge catheter (Becton-Dickinson) with a No. 7 stainless steel obturator (Ethicon). Chorionic villi sample sizes ranged from 3 to 75 mg with a mean of 21.4 ± 11.1 mg (mean ± SD). The maximum number of catheter insertions per patients was three (mean 1.6 ± 0.7).

A control population of 1335 phenotypically normal neonates from singleton pregnancies delivered at term

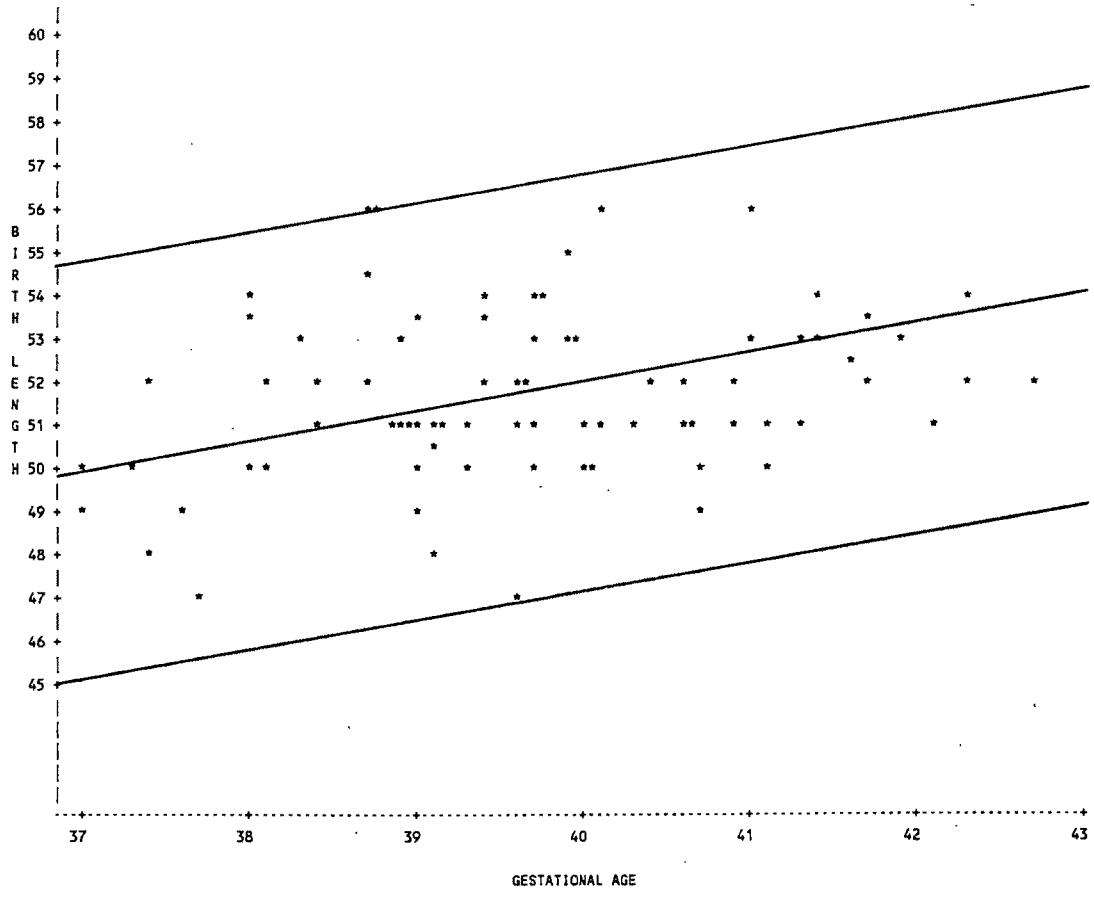

Fig. 2. The distribution of crown-heel lengths (measured in centimeters) versus gestational age of neonates from pregnancies having had chorionic villi sampling at 9 to 11 weeks' gestation. Predicted mean, ninety-fifth and fifth percentiles for the control population are superimposed on the graph.

of mothers between 35 and 45 years of age was evaluated in a similar manner to the study population. These control data were developed from a population of patients, similar to the patients having chorionic villus sampling, delivered at Cedars-Sinai Medical Center during the 2-year period immediately preceding the clinical application of chorionic villus sampling at this center. The means and standard deviations were calculated for maternal age, gestational age, birth weight, crown-heel length, and ponderal index in each population and compared by means of Student's *t* test.

In addition, the predicted mean, ninety-fifth, and fifth percentiles for the control population were determined and the distribution of each variable in the study population was plotted against gestational age. With an alpha error level of 0.05 and beta error level of 0.1, the sample size necessary to detect a 5% difference in population means was calculated for the measured variables and achieved before analysis.

Results

The differences between all variables evaluated for both study and control populations at delivery were not statistically significant. These values and their respective p values are summarized in Table I. The birth weights, crown-heel lengths, and ponderal indices were normally distributed for both chorionic villus sampling and control populations. The distributions of birth weight, crown-heel length, and ponderal index versus gestational age are plotted for the chorionic villus sampling patient population in Figs. 1, 2, and 3. The predicted mean, ninety-fifth and fifth percentiles for the control population are superimposed on the appropriate figures.

Comment

Chorionic villus sampling is rapidly emerging as a diagnostic alternative to amniocentesis. The advantage of chorionic villus sampling is that it is done in the first trimester and thereby provides earlier diagnosis. In cases in which the fetus is affected, earlier diagnosis allows for safer pregnancy termination. Initial concerns about chorionic villus sampling included a theoretic risk for placental complications (abruptio placentae or placenta previa) and intrauterine growth retardation attributable to trauma from insertion of the catheter

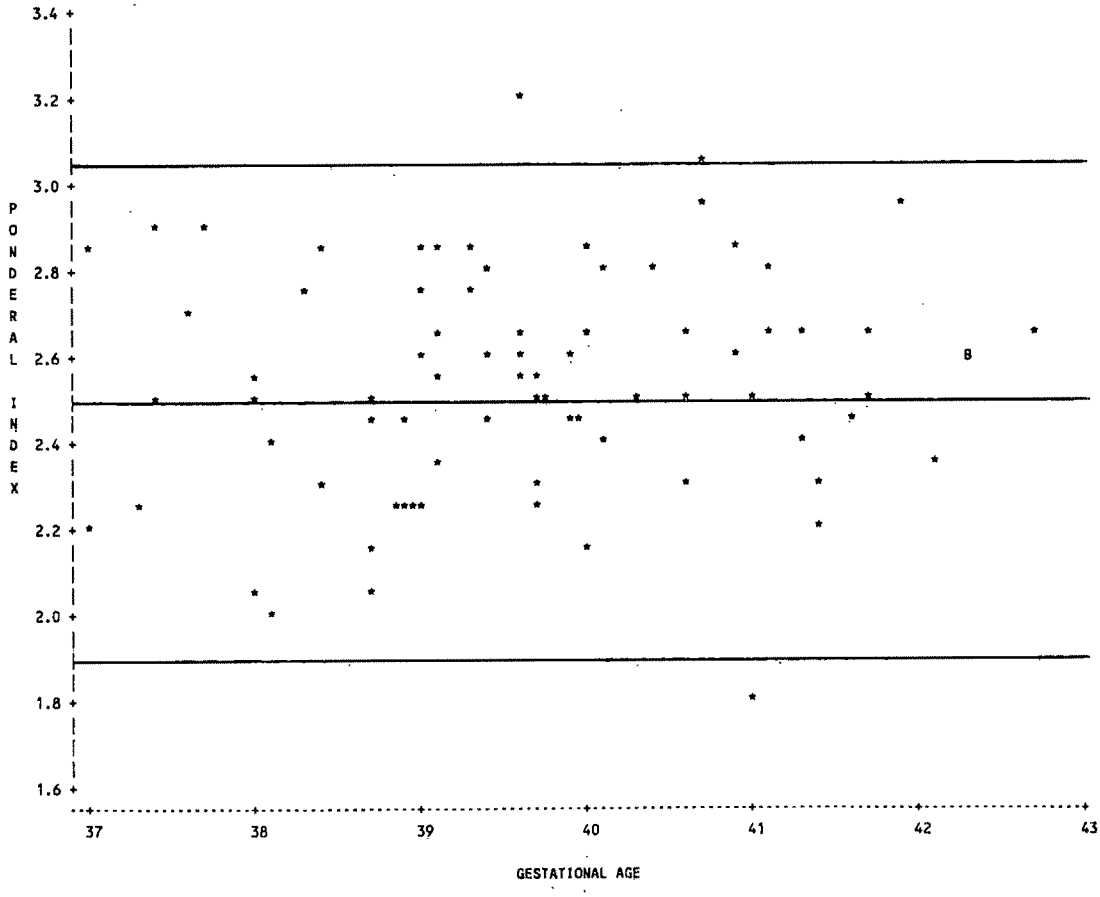

Fig. 3. The distribution of ponderal index versus gestational age of neonates from pregnancies having had chorionic villi sampling at 9 to 11 weeks' gestation. Predicted mean, ninety-fifth and fifth percentiles for the control population are superimposed on the graph.

and/or aspiration of sufficient chorionic villi to disrupt placental growth or function.[3] In a clinical evaluation of 300 births after chorionic villus sampling in Milan, Brambati et al.[2] reported that the frequencies of placental complications and low birth weight were similar to those found in the general Italian population. However, no statistical comparison between the mean birth weights in the chorionic villus sampling group and general population was presented.

Because many biologic factors including maternal age and parity as well as environmental factors are known to influence fetal growth,[4] the general population is not a suitable control group for the evaluation of the growth in neonates who have undergone chorionic villus sampling. The association of increased maternal age with parity and the high frequency of maternal age as an indication for chorionic villus sampling are factors that should be considered when evaluating growth after chorionic villus sampling, particularly when the most frequent indication for chorionic villus sampling at our institution (86%) and others[5, 6] is advanced maternal age (35 years or older at delivery). For this reason, both the chorionic villus sampling and control populations were restricted to patients aged 35 years or older at the time of delivery in our study. There was no significant increase in either maternal age or parity between control and chorionic villus sampling populations (Table I). The chorionic villus sampling and control groups in our study also were similar with respect to the gestational age at delivery. The percentage of patients undergoing amniocentesis in the control population is not known. However, since amniocentesis has not been shown to alter the outcome variables we were studying,[7] we believe that our control population is not biased by the absence of this information.

Our study demonstrates that there are no significant differences in birth weight, length, or proportionality at term between normal control infants and infants who undergo chorionic villus sampling at 9 to 11 weeks' menstrual age. It is noticeable that the p value for the ponderal index, which is a measurement of disproportionality in the neonate, is 0.07. However, the increase in this value is not a possible sign of growth retardation but reflects the opposite finding, resulting from a small increase in neonatal weight and a decrease in the neonatal length. The distribution of the variables of fetal

growth evaluated in this study are evenly distributed about the mean and no increase in values above or below the ninety-fifth and fifth percentiles for each variables are present (Figs. 1-3).

We calculated the sample size needed to detect a 5% difference in each of the outcome variables for an alpha error level of 0.05 and beta error level of 0.1. These sample sizes were exceeded for all variables studied. Therefore we conclude that patients undergoing first-trimester chorionic villus sampling are not at increased risk for the development of decreased fetal growth nor at increased risk for intrauterine growth retardation.

Umbilical blood waveforms in fetal surveillance of twins

Luis R. Saldana, M.D., Mary Catherine Eads, R.D.M.S., and Theresa R. Schaefer, R.D.M.S.
Cincinnati, Ohio

Umbilical arterial velocity waveforms were recorded in 69 pairs of twins by means of continuous-wave Doppler analysis and an Angioscan spectrum analyzer. A systolic/diastolic ratio was measured for each twin. The sum of the systolic/diastolic ratio was calculated and the difference between each twin was expressed as the delta systolic/diastolic ratio. Significant differences in delta systolic/diastolic and neonatal weight were previously set at 0.4 and 350 gm, respectively. Sonography was used for fetal age confirmation and diagnosis of fetal growth retardation. All neonates were weighed; at birth gestational age was assigned by Dubowitz criteria and categorized as adequate-, small-, or large-for-gestational age. The sensitivity, specificity, and predictive value of the delta systolic/diastolic ratio were determined. The perinatal implications of this test in the management of twin pregnancy are discussed. (Am J Obstet Gynecol 1987;157:712-5.)

Key words: umbilical artery waveforms, blood flow, twins

Twin pregnancy is characterized by high perinatal mortality and morbidity. A major causative factor for these difficulties is intrauterine growth retardation in one member of the twin dyad. Farmakides et al.[1] have shown that umbilical blood waveforms can be used to select the growth-retarded twin. The purpose of this study is to further elucidate the relationship of umbilical blood waveforms to fetal growth and well-being in twin dyads. An attempt was made to correlate differences in umbilical blood waveforms between members of the twin dyad to perinatal mortality and serious anomalies.

Material and methods

A total of 79 pairs of twins were detected by ultrasound before 26 weeks' gestation. Nine patients were excluded because of fetal death before 28 weeks (four) or noncompliance with the protocol (five). Sonographic examination helped to establish or confirm the gestational age. At birth, all babies were weighed and gestational age was assessed by a modification of the criteria developed by Dubowitz et al.[2] Twin dyads were then classified as AGA/AGA, AGA/SGA, SGA/SGA, or AGA/LGA according to the criteria of Naeye et al.[3] for multiple pregnancies. Clinicians referring patients were unaware of the results of umbilical velocimetry.

Table I. Predictability of Δsystolic/diastolic ratio for Δbirth weight

	AGA/AGA (N = 50)	*AGA/SGA (N = 10)*	*SGA/SGA (N = 4)*	*AGA/LGA (N = 4)*
S/D < 0.4				
Wt > 350 gm	39	1	0	0
Wt ≤ 350 gm	1*	0	0	3*
S/D ≥ 0.4				
Wt > 350 gm	6†	0	4†	0
Wt ≤ 350 gm	4	9	0	1

S/D = Systolic/diastolic ratio; Wt = birth weight.
*False negative. Predictive value of Δsystolic/diastolic ratio < 0.4 = 91%.
†False positive. Predictive value of Δsystolic/diastolic ratio = 0.4 = 42%.

All mothers had umbilical blood waveform determinations by means of a 4 MHz continuous-wave Doppler transducer (Angioscan) beginning at 20 to 24 weeks. Umbilical cords were identified by differing rates and by their location with the use of ultrasound just before the application of the Doppler transducer. The systolic/diastolic ratio described by Trudinger et al.[4] was determined for each twin at each visit. Patients were seen biweekly until the 28th week when systolic/diastolic ratios were determined weekly until delivery. Individual absolute systolic/diastolic ratios were recorded for each member of the twin dyad. The difference between the systolic/diastolic values for each twin was determined. The sum of the differences was averaged and called the delta (Δ) systolic/diastolic ratio. A Δsystolic/diastolic ratio ≥ 0.04 was previously established[1] as being associated with a significant birth weight difference (Δ birth weight) of 350 gm or more in twin dyads. We attempted to confirm this relationship. In addition, each twin dyad was scrutinized for the absolute systolic/diastolic values of its members and their possible relation to perinatal death and serious anomalies.

Sonograms for calculation of gestational age were done biweekly during this period of time (28 to 40 weeks). However, if absolute systolic/diastolic ratios were abnormal or previous evidence of divergent growth was present, the sonogram was repeated weekly. We compared the Δsystolic/diastolic ratio with the sonographic evidence for divergent fetal growth. We relied primarily on the birth weight for the analysis of Δsystolic/diastolic ratio sensitivity and predictive value. Ultrasound examination consisted of biparietal diameter, femur length, abdominal circumference, and estimation of fetal weight by the method of Warsof et al.[5] The average number of sonograms was five per dyad.

Results

A total of 69 patients were delivered in the third trimester. Of these, 64 patients were delivered within 5 days of the last blood waveform study. Four patients were delivered 6 to 10 days from the last systolic/diastolic determination and only one was delivered 14 days after the last umbilical blood waveform study. The most frequent type of twin dyad was appropriate for gestational age (AGA/AGA), which was found in 51 of 69 patients (74%). Dyads in which one was AGA and the other small for gestational age (SGA) were found in 10 cases (14%), whereas SGA/SGA and AGA/large for gestational age (LGA) dyads had a 6% frequency each. Frequency distributions and predictive values are shown in Table I.

AGA/AGA dyads (N = 51)

ΔSystolic/diastolic ratio < 0.4 and intradyad Δbirth weight < 350 gm. Thirty-nine sets of twins fell in this category. One stillbirth occurred in a twin dyad in which serial systolic/diastolic ratios averaged 3.4 for both fetuses in biweekly tests from 28 to 35 weeks. Absolute systolic/diastolic ratios over 3.0 persisted at 36 weeks but the Δsystolic/diastolic ratio = 0.22 and Δbirth weight = 70 gm. Divergent fetal growth was suggested by serial sonograms. A nonstress test (NST) was nonreactive 2 days before the death of the stillborn twin. Delivery was delayed by an immature lecithin-sphingomyelin (L/S) ratio. The fused, diamniotic placenta showed triploidy and molar degeneration. Another dyad had a stillbirth at 34 weeks. The Δsystolic/diastolic ratio was 0.17 and the Δbirth weight was 110 gm. The stillborn baby had extensive subarachnoid hemorrhage and hemothorax. The surviving twin had thrombocytopenia and disseminated intravascular coagulation. The absolute systolic/diastolic ratios for each twin were all above 3.0.

Review of serial sonograms revealed concordant fetal growth in 24 patients (63%) and discordant fetal growth in 14 dyads (37%). The latter are false-negative values yielded by sonogram examinations. Discordant fetal growth by sonography was present if the biparietal diameter difference was ≥4 mm after 28 weeks or the estimated difference in Δbirth weight ≥350 gm using the method of Warsof et al.[5] In five patients we thought that biparietal diameter (three) or femur length (two) measurements were unreliable or unobtainable because of fetal position.

ΔSystolic/diastolic ratio ≥ 0.4 and Δbirth weight ≥ 350 gm. There were four patients in this subset. These dyads had a relatively high incidence of death and serious anomalies. One dyad had Down's syndrome in both babies (patient had refused genetic amniocentesis). The Δsystolic/diastolic ratio was 0.5 and the Δbirth weight was 377 gm. Sonograms had detected discordant fetal growth starting at 29 weeks. These infants survived the neonatal period. Another dyad had concordant growth detected by sonography but megalocystis was noted at 26 weeks. The patient returned in premature labor at 30 weeks with a Δsystolic/diastolic ratio of 0.8 and Δbirth weight of 361 gm. The smaller twin died of pulmonary hypoplasia. Absolute systolic/diastolic ratios in this baby were 4.1 and 3.7.

The ultrasound measurements showed concordant growth in three of these four dyads. At birth, the average Δbirth weight = 412 gm (range 370 to 540 gm). It was impossible to obtain a biparietal diameter twice in two fetuses because of fetal position or extreme deflexion of fetal head.

ΔSystolic/diastolic ratio ≥ 0.4 and Δbirth weight < 350 gm. There were seven dyads in this group. These represent false-positive results in the expected relationship between Δsystolic/diastolic ratio and Δbirth weight. Sonograms showed divergent growth in four of these seven dyads (57% false positive). All three sonographic parameters (biparietal diameter, femur length, and abdominal circumference) were obtained. The average Δbirth weight was 137 gm (range 60 to 250 gm). Careful review of individual systolic/diastolic ratios showed only two dyads with absolute systolic/diastolic ratios over 3.0 after 28 weeks. One dyad had a twin with absolute systolic/diastolic ratio of 3.0 but Δsystolic/diastolic ratio of 0.5 for the dyad. This twin suffered neonatal death caused by a single ventricle and tricuspid insufficiency. Another dyad had one twin with absolute systolic/diastolic ratio of 3.0 and Δsystolic/diastolic ratio of 0.7 for the dyad. The mother had gestational diabetes with hyperglycemia.

ΔSystolic/diastolic ratio < 0.4 and Δbirth weight ≥ 350 gm. There was only one AGA/AGA dyad with a false-negative value. The Δsystolic/diastolic ratio was 0.14 for the dyad and Δbirth weight was 410 gm. All individual systolic/diastolic values for each twin were less than 3.0 after 28 weeks. Ultrasonography correctly detected divergent fetal growth at 25 weeks and thereafter.

In summary, the AGA/AGA group contains three dyads with severe anomalies. Two of these dyads had neonatal deaths. The other dyad had Down's syndrome. Two other AGA/AGA dyads had a single stillbirth each. In these two cases the Δsystolic/diastolic ratio < 0.4, but the absolute systolic/diastolic ratio consistently exceeded 3.0 after 28 weeks.

AGA/SGA dyads. There were 10 dyads in this group with an average Δbirth weight of 635 gm overall.

ΔSystolic/diastolic ratio ≥ 0.4 and Δbirth weight ≥ 350 gm. There were nine dyads in this subset indicating a true-positive rate of 100% for Δsystolic/diastolic ratio ≥ 0.4. Only one dyad had a smaller twin with absolute systolic/diastolic ratio in the normal range after 28 weeks. Ultrasonography also forecasted divergent growth in seven of these nine dyads (78%). Only in one occasion was a biparietal diameter not obtainable.

ΔSystolic/diastolic ratio < 0.4 and Δbirth weight < 350 gm. One dyad had Δsystolic/diastolic ratio of 0.2 and Δbirth weight of 110 gm. There was only one absolute systolic/diastolic ratio of 3.0 after 28 weeks. A sonogram had forecasted a significant Δbirth weight of 375 gm 2 days before birth.

This group had no mortality and no anomalies were found.

SGA/SGA dyads. There were four dyads in this group. The Δsystolic/diastolic ratio was equal to or greater than 0.4 in all dyads. The average Δbirth weight was 35 gm (range zero to 110 gm). These were all false-positive values for Δsystolic/diastolic ratio in relation to Δbirth weight. Review of absolute systolic/diastolic values revealed that these fetuses had the highest individual systolic/diastolic values in the series (average absolute systolic/diastolic ratio = 4.0; range 3.0 to 5.0). The cesarean section rate was 100% for this subset. Sonograms showed concordant growth in three dyads and divergent growth in one dyad (75% accuracy).

LGA/AGA dyads. There were four dyads in this group and it had the largest Δbirth weight values (range 400 to 630 gm) for the series. There was one dyad with a Δsystolic/diastolic ratio of 0.7 and a Δbirth weight of 630 gm (true positive). All others had false-negative Δsystolic/diastolic ratio values. These fetuses had the lowest absolute systolic/diastolic values.

Predictive value. Table I shows a high predictive value (91%) of Δsystolic/diastolic ratio < 0.4 for confirming concordant fetal growth. Divergent fetal growth was more difficult to detect by Δsystolic/diastolic ratio. There was only 42% predictive value for Δsystolic/diastolic ratio = 0.4.

Comment

Our study indicates that umbilical blood waveforms are a useful adjunct in the management of twin pregnancies. We found the AGA/AGA twin dyad was the most common dyad (74%) in our series. The entire perinatal death and all serious anomalies were also found in this group. This was surprising since we expected both the AGA/SGA and SGA/SGA dyads to have a worse prognosis. In two dyads with individual still-

births, persistent absolute systolic/diastolic ratios over 3.0 suggested placental dysfunction. The Δsystolic/diastolic ratio was not able to differentiate the twin at risk in these two dyads but there was no significant Δbirth weight present. Two neonatal deaths were found among the four AGA/AGA dyads with Δsystolic/diastolic ratio ≥ 0.4 and Δbirth weight ≥ 350 gm. These latter findings agreed with our expectations for the test as a sign of placental dysfunction and an indicator of divergent fetal growth.[6] Ultrasound examinations were the least reliable (59% accuracy) among these AGA/AGA dyads.

The Δsystolic/diastolic ratio correctly detected significant weight differences in 9 of 10 AGA/SGA fetuses and identified the one dyad with Δbirth weight < 350 gm in that group. Serial sonograms had 78% accuracy in this group. Although the seven SGA/SGA dyads showed falsely high Δsystolic/diastolic ratio in all cases, review of the absolute systolic/diastolic values showed that they had persistently high absolute systolic/diastolic ratios.

All four SGA/SGA dyads had falsely high Δsystolic/diastolic ratios with no significant birth weight differences or perinatal morbidity. This was confusing but the number is small. A poor growth potential for both twins in these dyads is a possible explanation. Although these twins had a high cesarean section rate, no severe perinatal anomalies were noted. The large weight differences in the four AGA/LGA dyads were also not reliably predicted by the Δsystolic/diastolic ratio. A likely explanation is that changes in placental resistance are unlikely to be present in this situation.

Comparison with ultrasound findings revealed that the Δsystolic/diastolic ratio was a better predictor of Δbirth weight except for the SGA/SGA dyads. Difficulties in measuring the biparietal diameter and femur length in some dyads was frustrating. Both techniques can also be affected by large shifts in fetal lie. It appears that both the Δsystolic/diastolic and the absolute systolic/diastolic ratios must be carefully determined and followed serially in all cases of twin gestation. We would expect that pulsed Doppler ultrasound may further increase the applicability of this useful variable.

Umbilical cord size and amniotic fluid volume in prolonged pregnancy

Richard K. Silver, M.D., Sharon L. Dooley, M.D., Ralph K. Tamura, M.D., and Richard Depp, M.D.

Chicago, Illinois

Expectant management of prolonged pregnancy is predicated on reassuring biophysical testing. However, even the combination of a reactive nonstress test and normal amniotic fluid volume may not prevent subsequent morbidity. To test the hypothesis that diminished cord Wharton's jelly incurs risk of peripartum cord compression in addition to decreased amniotic fluid, 68 patients with confirmed gestational age ≥41 weeks were evaluated prospectively with semiweekly nonstress tests and weekly ultrasound examinations. Amniotic fluid volume was assessed, and umbilical cord diameter was measured and then correlated with the quantity of Wharton's jelly at delivery, determined by cord circumference. A significant correlation between cord circumference and umbilical cord diameter was observed, even in those patients with decreased amniotic fluid volume. Either an amniotic fluid volume <3.8 cm or an umbilical cord diameter <1.6 cm was associated with significant cord compression patterns. Peripartum morbidity was greatest in the presence of a smaller cord and decreased fluid, suggesting a synergism between these two factors for the risk of cord compression in prolonged pregnancy. (Am J Obstet Gynecol 1987;157:716-20.)

Key words: Prolonged pregnancy, Wharton's jelly, amniotic fluid volume

Protocols designed to permit expectant management of prolonged pregnancy have relied on an increased frequency of standard biophysical evaluations. Although semiweekly nonstress tests (NSTs) have been used to ensure fetal well-being, it has been recognized that a reactive NST with variable decelerations can be associated with an unfavorable pregnancy outcome.[1] This finding may relate to the fact that cord compression rather than placental dysfunction accounts for most of the perinatal morbidity in prolonged pregnancy.[2] Furthermore, the risk of cord compression has been related to diminished amniotic fluid volume.[3] To account for this factor, periodic ultrasound assessment of amniotic fluid has been incorporated into most management schemes.[3-6] However, when evaluated prospectively, even the combination of reassuring heart rate testing and adequate amniotic fluid has been associated with significant perinatal morbidity.[7]

Although a normal amount of amniotic fluid has been interpreted as protective against cord compression, the amount of Wharton's jelly may also play a role. Chasnoff and Fletcher[8] provided direct evidence for this role with an in vitro cord model. With artificially knotted cords, they observed an inverse relationship between the amount of Wharton's jelly and the pressure required to perfuse the umbilical vein. As the amount of Wharton's jelly has been shown to decrease with advancing gestational age, we hypothesize that decreased cord Wharton's jelly incurs risk of perinatal cord compression in prolonged gestation. Accordingly, this prospective study was designed with the following objectives: (1) to establish the feasibility of ultrasound measurement of umbilical cord diameter, (2) to relate ultrasound cord diameter to direct measurement of the amount of Wharton's jelly at delivery, (3) to correlate amniotic fluid volume and cord diameter measured by ultrasound with the incidence and severity of variable fetal heart rate decelerations before and during labor, and (4) to determine whether the combination of decreased umbilical cord size and diminished amniotic fluid volume better identifies patients at risk for perinatal morbidity in prolonged pregnancy.

Material and methods

Patients entered into this study were recruited from the antenatal testing unit at Prentice Women's Hospital of Northwestern University from June 1 to Dec. 30, 1986. Informed consent was obtained immediately before biophysical testing. All pregnancies were ≥41 weeks at the time of study entry on the basis of reliable menstrual data, early examination, and/or early ultrasound assessment. After NST completion but before interpretation, ultrasound examination was performed (640 Linear Scanner, Corometrics). Umbilical cord di-

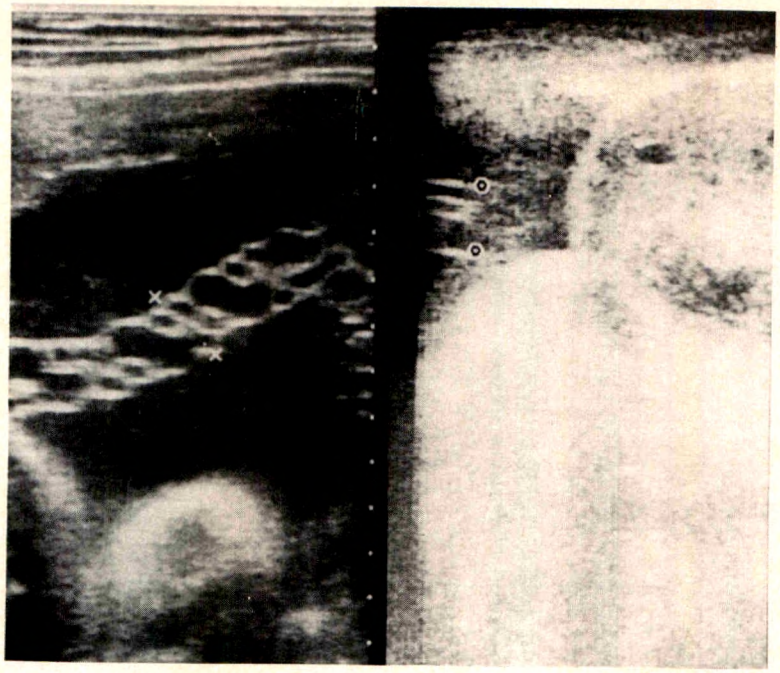

Fig. 1. Illustration of measured cord diameter by ultrasound with both normal and decreased amniotic fluid volume.

ameter was obtained by imaging a longitudinal segment of cord (Fig. 1) and averaging three diameter measurements. Amniotic fluid volume was assessed with the patient in the supine position with lateral uterine displacement. Four uterine quadrants were identified with the midline of the maternal abdomen and the level of the umbilicus used as vertical and horizontal boundaries, respectively. After the largest pocket of fluid in each quadrant was identified, the mean of the three largest vertical measurements was calculated and used to represent amniotic fluid volume. For clinical purposes, amniotic fluid was subjectively categorized as normal, low normal, or oligohydramnios, and this interpretation was made available to the attending physician with the NST results. Umbilical cord diameter and amniotic fluid volume measurements were used only for the purposes of the study. Ultrasound measurements were obtained weekly and NSTs were performed semiweekly until delivery.

To directly measure the quantity of Wharton's jelly at delivery, a segment from the middle third of each cord was rinsed, stripped of blood, and frozen in an occlusive, polyethylene bag at $-20°$ C. Each frozen segment was cross-sectioned at a 90-degree angle at three selected locations, avoiding varicosities. The cut ends were stained with methylene blue and multiple imprints made on paper. Circumference was measured on each imprint in triplicate by means of a digitizer (Model 12405-1, Numonics Corp.). The cord circumference measured in centimeters was derived from the average measurement of six imprints, two from each of the three cross sections.

Antepartum variable decelerations were defined as a decrease in fetal heart rate of $\geq$15 beats/min for at least 15 seconds' duration. The intrapartum fetal heart tracings were interpreted in a standard fashion with the following objective criteria to quantify variable decelerations: (1) Prolonged variable decelerations were defined as >2 minutes in duration with a nadir <90 beats/min whereas severe prolonged variables lasted >4 minutes with a <70 beat/min nadir; (2) total variable deceleration duration was quantified by adding the total deceleration time at <90 beats/min throughout labor (excluding individual decelerations <30 seconds).

Ultrasound and in vitro cord measurements, as well as NST and intrapartum heart rate interpretation, were all performed blinded to each other and to outcome. Data were analyzed with the Statistical Package for Social Sciences (Version X) with χ^2 analysis for discrete variables and t tests (two-tailed) and regression analysis for continuous data.

Results

Sixty-eight of the 72 patients enrolled had complete data obtained and made up the study population. Umbilical cord segments and monitor tracings were not recovered in two patients each. Selected patient characteristics are shown in Table I. The mean gestational age at delivery was 294 days (range 287 to 302 days)

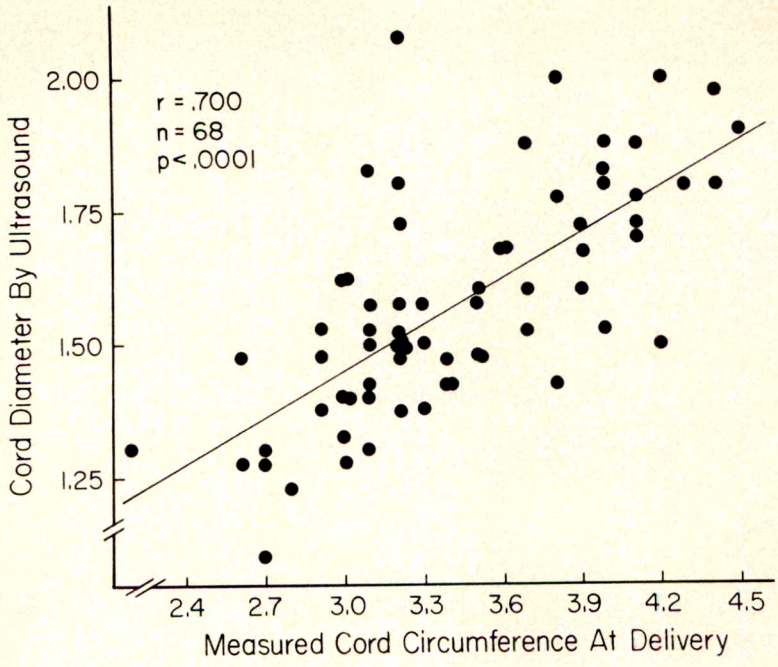

Fig. 2. The relationship of cord diameter by ultrasound to cord circumference at delivery.

Table I. Selected characteristics of 68 patients with prolonged pregnancy

	No.	*%*
Ultrasound examination to delivery interval (days) (mean ± SD)	2.4 ± 2.2	
Duration of intrapartum monitoring (hr) (mean ± SD)	10.5 ± 7.0	
Meconium-stained amniotic fluid	22	(32.3)
Nuchal or shoulder cord at delivery	22	(32.3)
Delivery beyond 42 wk	40	(58.8)
Delivery for fetal heart rate indications		
Cesarean section	10	(14.7)
Operative vaginal	9	(13.2)

and 19 deliveries (27.9%) were performed for fetal heart rate indications. Nine of these were vaginal deliveries (low forceps, N = 6; midforceps, N = 3), in which emergent intervention during the second stage was required as a result of nonremediable, prolonged variable decelerations. Although abnormal cord position at delivery was common in the entire series, there was no association between this finding and either the presence of variable decelerations or fetal heart rate indication for delivery.

Ultrasound measurements revealed a mean amniotic fluid volume of 3.8 cm (range 1.2 to 6.5 cm) and a mean umbilical cord diameter of 1.6 cm (range 1.1 to 2.1 cm). Nineteen and three patients had mean amniotic fluid volume values of <3 and <2 cm, respectively. The mean in vitro cord circumference was 3.4 cm (range 2.2 to 4.5 cm). A significant correlation between in vitro and ultrasound cord measurements was found (Fig. 2). This correlation was present even if analysis was limited to smaller cords (umbilical cord diameter <1.4; N = 19, r = 0.65, p = 0.0027), or those patients with less amniotic fluid (amniotic fluid volume <3.4; N = 27, r = 0.68, p = 0.0001).

Table II demonstrates the impact of amniotic fluid alone on the risk of peripartum cord compression. There were no statistically significant differences when patients were grouped according to amniotic fluid volume being greater or less than 1, 2, or 3 cm. In similar analyses relating umbilical cord diameter to peripartum cord compression, the same trends were seen although significance was not reached. However, there was a significantly smaller mean umbilical cord diameter in the 11 patients with antepartum variable decelerations compared with those without (1.4 versus 1.6; $p < 0.05$). Neither amniotic fluid volume nor umbilical cord diameter related to the incidence of meconium, abnormal

cord location, or the interval from rupture of membranes to delivery.

The interaction between amniotic fluid volume and umbilical cord diameter is shown in Table III. The 23 patients with both a smaller umbilical cord diameter and lower amniotic fluid volume had the highest rate of cord compression during labor and were most likely to be delivered for that reason. When these same patients were compared with all others (N = 45), significant increases in the presence of prolonged variables (56.5% versus 26.7%; $p < 0.05$) and fetal heart rate indication for delivery (43.5% versus 20.0%; $p < 0.05$) were also observed. As seen in Table III, although the individual categories have small numbers of patients, a consistent trend of increased morbidity was observed when either fluid volume or cord size was below the population mean. Even the presence of a larger cord was associated with frequent delivery for fetal heart rate indications when amniotic fluid volume was decreased (35.7% versus zero, $p < 0.05$). This same combination was also associated with a lower cord arterial pH at delivery when compared with the 14 patients with both a larger cord and higher fluid volume (7.22 versus 7.31, $p < 0.01$).

The predictive value of amniotic fluid volume, umbilical cord diameter, and the presence of antepartum variable decelerations was assessed with regard to the likelihood of delivery for fetal heart rate abnormalities. In this analysis, sensitivity was lowest with only the presence of variable decelerations on NST used as a discriminator (N = 11, 42%); intermediate with only amniotic fluid volume < 3.8 cm (N = 37, 79%); and highest when a smaller cord and lower fluid volume were present (N = 23; 100%). The combination of all three findings was also 100% sensitive and maximized both specificity (93%) and predictive value (positive = 83%, negative = 100%).

Comment

In this series, ultrasound measurement of the umbilical cord was accomplished without difficulty, even in those cases with decreased amniotic fluid. The cor-

relation between sonographic and in vitro cord measurements demonstrates that the cord diameter observed on ultrasonography reflects the actual quantity of Wharton's jelly, although the former included the contribution of fetal blood.

Instead of prospectively assessing amniotic fluid subjectively (as normal, low, or oligohydramnios) or categorically (as <2 or <1 cm vertical pockets), we chose to use a continuous measure for two reasons: to avoid the unsubstantiated bias that a threshold vertical measurement exists (e.g., 2 cm) above which amniotic fluid is assuredly normal, and (2) to satisfy our expectation that many pregnancies beyond 41 weeks would have relatively diminished fluid that would be inappropriately categorized as normal by traditional definitions. In fact, using our population's mean vertical measurement (3.8 cm) as an arbitrary breakpoint, we observed a significant excess of intrapartum cord compression patterns in patients with amniotic fluid volume below this value, although most of these patients had amniotic fluid volume ≥2 cm. The shortcomings of a categoric definition for decreased amniotic fluid have also been identified by other investigators.[9-11]

To assess the impact of umbilical cord size and amniotic fluid volume together, four sets of circumstances were analyzed. If our hypothesis were true, the most vulnerable combination would be a small cord and low fluid volume (N = 23). Indeed, this setting was found to be associated with the highest risk for significant intrapartum cord compression, although amniotic fluid volume appeared to be the most important predictor of intrapartum morbidity. Using our results to assess the predictive value of these factors separately and in combination, we found that the presence of antepartum variable decelerations, a smaller cord, and lower fluid volume best identified intrapartum morbidity. However, as the number of patients with this combination was small, prospective confirmation of these predictive values is needed.

Previous studies have shown that the water content of Wharton's jelly decreases progressively in late gestation[12] and that water content is significantly correlated with the amount of Wharton's jelly as measured by cord circumference.[13] These findings provoke speculation as to a relationship between water content in both the cord and amniotic fluid. Indeed, a limited correlation between umbilical cord diameter and amniotic fluid volume was observed in this study ($r = 0.25$; $p = 0.038$). However, almost as many larger cords were associated with lower fluid volume (N = 14) as the opposite (N = 17). Therefore it is unlikely that both changes occur simultaneously or at the same rate. Although an interrelation between these two factors is an attractive hypothesis, it cannot be firmly established from these data. A delineation of the biochemical, hormonal, or mechanical factors that regulate the quantities of amniotic fluid and Wharton's jelly may provide a better understanding of these issues.

In summary, antepartum cord assessment appears to be feasible and the results obtained correlate with actual in vitro measurements. We have not identified an absolute umbilical cord diameter or amniotic fluid volume below which risk can be anticipated or above which well-being is assured. However, patients with values below the respective means in this study experienced significant antenatal and intrapartum cord compression, and the combination of umbilical cord size and amniotic fluid quantity appeared to be synergistic with regard to significant fetal heart rate abnormalities in labor. The introduction of umbilical cord measurement as an additional antenatal test during prolonged pregnancy awaits prospective evaluation.

The origin of increased serum iron in pregnancy-induced hypertension

Philip Samuels, M.D., Elliott K. Main, M.D., Michael T. Mennuti, M.D., and Steven G. Gabbe, M.D.

Philadelphia, Pennsylvania

Serum iron was measured in 30 patients with pregnancy-induced hypertension and 24 normal pregnant women. The mean iron concentration was significantly higher in the group with pregnancy-induced hypertension (111 ± 26 μg/ml) than in the controls (69 ± 17 μg/ml) ($p < 0.0001$). Readily available laboratory variables were used to determine whether the increased serum iron was the result of (1) hemolysis, (2) hepatocellular injury, or (3) intravascular volume contraction leading to hemoconcentration. It appears that a clinically silent, ongoing hemolytic reaction is responsible for the increase in serum iron seen in patients with pregnancy-induced hypertension. (Am J Obstet Gynecol 1987;157:721-5.)

Key words: Hemolysis, pregnancy-induced hypertension, serum iron

Pregnancy-induced hypertension may be difficult to distinguish from chronic hypertension and other systemic illnesses associated with increased blood pressure. Entman et al.[1] have previously demonstrated that serum iron is increased in patients with pregnancy-induced hypertension. They have proposed that an elevation in serum iron concentration may be a better discriminator than other variables, including uric acid, in differentiating pregnancy-induced hypertension from other forms of hypertension.[1, 2] However, the cause of this increased serum iron is unknown. The body's major stores of iron are located in red blood cells and in the liver.[3] The increase in iron concentration could be the result of destruction of red blood cells or hepatocellular damage. Serum iron might also be elevated as a result of intravascular volume contraction resulting in hemoconcentration. This study was undertaken to determine the cause of this increase in serum iron. We used readily available laboratory variables that could help us to determine whether hemolysis, hepatocellular damage, or hemoconcentration were responsible. An understanding of this phenomenon might provide further insight into the pathophysiology of this disorder.

Methods

We studied 30 patients with pregnancy-induced hypertension and 24 normal patients who came to the Hospital of the University of Pennsylvania between February 1985 and August 1986. Strict criteria were used to diagnose pregnancy-induced hypertension. All patients with pregnancy-induced hypertension (1) had a diastolic blood pressure of at least 90 mm Hg recorded in the left lateral decubitus position on two occasions at least 6 hours apart; (2) had normal blood pressure recordings in the first or second trimester when available; (3) had ≥2+ proteinuria on a catheterized specimen; (4) had a serum uric acid concentration ≥6.0 mg/dl; (5) were primigravidas; and (6) had no history or laboratory evidence of hypertension, renal disease, or collagen vascular disease. Only five patients with pregnancy-induced hypertension had sustained diastolic blood pressures ≥110 mm Hg.

Control patients (1) were primigravidas; (2) were normotensive throughout their prenatal course and the puerperium; (3) had trace or less proteinuria on a clean-catch specimen; (4) had a serum uric acid concentration ≤4.7 mg/dl; and (5) had no history or laboratory evidence of a systemic disease.

All patients were studied, with the use of standard laboratory techniques, for evidence of hemolysis (haptoglobin, plasma-free hemoglobin, and reticulocyte count); hepatocellular damage causing release of iron (alanine aminotransferase, aspartate aminotransferase, gamma glutamyl transferase, or serum ferritin); and intravascular volume contraction leading to hemoconcentration (hemoglobin and blood urea nitrogen:creatinine ratio). Two other measured variables, total bilirubin and lactate dehydrogenase (LDH), could represent either hemolysis or hepatocellular damage. Approximately 20 ml of blood was obtained by venipuncture in test tubes containing the appropriate anticoagulant or preservative for the tests being performed.

Table I. Characteristics of patients studied

	Pregnancy-induced hypertension (*n* = 30)	*Normal* (*n* = 24)
Mean age (yr)	21.8	22.4
Age range (yr)	16-27	19-27
Mean gestation (wk)	35.8	37.5
Gestation range (wk)	28-40	34-42
Black/white	23/7	19/5
Primigravidas	All	All
No prenatal care	5	0

All samples were processed within 4 hours of collection. All blood was drawn before the onset of labor and before the patients with pregnancy-induced hypertension received magnesium sulfate. Blood urea nitrogen, serum creatinine, gamma glutamyl transferase, and total bilirubin determinations were made with a commercial kit for the Ektachem-700 (Kodak) analyzer. Aspartate aminotransferase, alanine aminotransferase, and LDH determinations were made with the use of a kit for the Encore (Baker) analyzer. Haptoglobin was determined with a commercial kit for the Cobas Bioanalyzer (Roche). Serum iron was assayed by the controlled potential colorimetry method with the Ferrochem 3050 Iron and TIBC analyzer (Environmental Science Associates). Plasma hemoglobin was determined by the ortho-tolidine, acetic acid method and read in a spectrophotometer at 625 nm.[4] Serum ferritin was analyzed by the Ferrizyme EIA kit with the Quantum II analyzer. Reticulocytes were stained with a vital stain and counted manually.

Statistical analysis was performed by means of the Statworks program for the Apple Macintosh Plus computer. Means were compared with the two-tailed Student *t* test. Correlations between serum iron and other variables were determined with the use of linear regression. We also used multiple linear regression to determine the proportion of serum iron attributable to the subgroups of hemolysis, hepatocellular injury, and intravascular volume contraction.

Results

The groups were closely matched for age, race, and gravidity (Table I). The average length of gestation was shorter in the group with pregnancy-induced hypertension than in the control group (35.0 ± 3.7 weeks versus 37.5 ± 2.5 weeks) ($p = 0.07$, Student's *t* test). Whereas five of the patients with pregnancy-induced hypertension had not sought prenatal care, all of the control patients had been under the care of a physician during pregnancy.

Only five patients met blood pressure criteria for severe pregnancy-induced hypertension (persistent diastolic blood pressure ≥110 mm Hg). Because serum iron levels did not correlate with the degree of hypertension or proteinuria, we did not distinguish between patients with mild and severe pregnancy-induced hypertension in this study. None of the patients studied became eclamptic.

We found that patients with pregnancy-induced hypertension have a higher serum iron concentration (111 ± 26 μg/dl) when compared with normal control pregnancies (69 ± 17 μg/dl) ($p < 0.0001$). This observation confirms the findings of Entman et al.[1] The mean of each variable studied in patients with and without pregnancy-induced hypertension and the statistical significance of the differences are displayed in Table II. Using the technique of linear regression, we determined the correlation between serum iron concentrations and the levels of the various variables studied in patients with pregnancy-induced hypertension. The results of linear regression analysis are shown in Table III.

The strongest correlations were between serum iron and LDH, plasma hemoglobin, haptoglobin, and the reticulocyte count. These correlations are graphically depicted in Fig. 1. There was also a strong correlation between total bilirubin and serum iron concentrations (coefficient of correlation = 0.67). Each patient had a direct bilirubin determination performed. Only two patients had concentrations exceeding 0.2 mg/dl, one being 0.3 mg/dl and the other 0.4 mg/dl.

Parameters of hepatocellular damage correlated poorly with serum iron levels (Table III). The relationships between serum iron and the indices of volume contraction were not significant.

We then used multiple linear regression to determine the proportion of the serum iron in patients with pregnancy-induced hypertension that could be attributed to hemolysis, hepatocellular damage, and volume contraction. The results, shown in Table IV, clearly demonstrate that hemolysis is the largest contributor to the increase in serum iron seen in the patients with pregnancy-induced hypertension we studied.

Comment

We have confirmed the observation that serum iron is increased in patients with pregnancy-induced hypertension.[1] A variety of laboratory parameters and statistical analyses suggest that this increase in iron arises from a mild, ongoing intravascular hemolysis. We did not separate patients with mild and severe pregnancy-induced hypertension because serum iron levels did not correlate with severity of disease. However, only five patients met blood pressure criteria for severe pregnancy-induced hypertension, and only four of them had a platelet count below 150,000/mm³. None

Table II. Comparison of parameters studied in patients with and without pregnancy-induced hypertension

	Normal (n = 24)	*Pregnancy-induced hypertension (n = 30)*	*p Value**
Serum iron (μg/dl)	69 ± 17	111 ± 26	<0.0001
Hemolysis			
Plasma hemoglobin (mg/dl)	0.4 ± 0.3	3.5 ± 1.7	<0.0001
Haptoglobin (mg/dl)	120 ± 30	70 ± 25	<0.0001
Reticulocyte (%)	1.3 ± 0.8	2.3 ± 0.8	<0.0001
Hemolysis or liver			
LDH (IU/L)	210 ± 35	315 ± 95	<0.0001
Total bilirubin (mg/dl)	0.6 ± 0.2	1.1 ± 0.2	<0.0001
Liver			
ALT (IU/L)	14 ± 7	17 ± 9	0.413
AST (IU/L)	15 ± 5	16 ± 11	0.672
GGT (IU/L)	18 ± 4	13 ± 7	0.004
Ferritin (ng/ml)	25 ± 11	30 ± 11	0.078
Volume contraction

had a depressed fibrinogen level. Therefore frank hemolysis, as seen with the fulminant disseminated intravascular coagulopathy that may complicate severe pregnancy-induced hypertension, is unlikely to have contributed significantly to this process.

Haptoglobin, plasma hemoglobin, and reticulocytosis are solely indicative of hemolysis. However, LDH can originate from red blood cells or the liver. We did not have the ability to distinguish between these isoenzymes. No other parameter of liver function correlated with serum iron, so we believe the difference in LDH was probably a result of hemolysis.

Total bilirubin can also be the result of either hemolysis or hepatocellular injury. With hemolysis, the indirect component of bilirubin is generally elevated because it saturates the conjugating enzyme mechanism. With liver dysfunction, the direct component is often elevated because conjugated bilirubin cannot be excreted. Because the major portion of the bilirubin was unconjugated in the patients we studied, we believe that this represents hemolysis.

Serum ferritin, a protein that complexes iron, is the major storage form of iron found in the liver, spleen, and bone marrow.[5] Ferritin is an accurate reflection of the body's iron stores unless there is hepatocellular damage with release of stored ferritin into the circulation. Although Entman et al.[6] noted an increase in serum ferritin in patients with pregnancy-induced hypertension, it was not sufficient to account for their

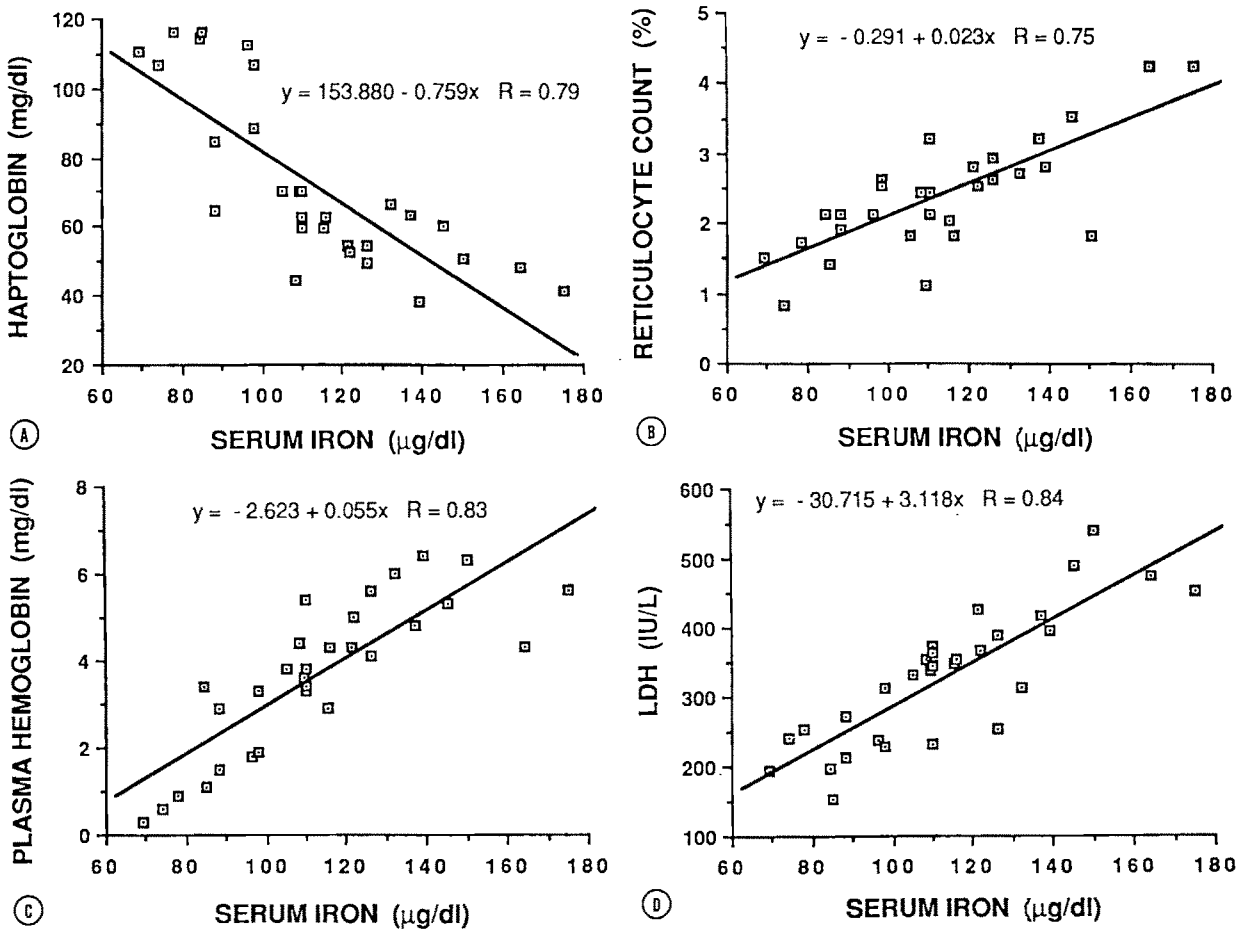

Fig. 1. Correlation between serum iron concentration and parameters of hemolysis in 30 patients with pregnancy-induced hypertension. Linear regression was used to determine correlations of coefficient between the concentration of serum iron and the level of haptoglobin (**A**), reticulocyte count (**B**), plasma-free hemoglobin (**C**), and lactate dehydrogenase (**D**).

observed increase in serum iron. Our patients did not show this increase in serum ferritin. In our series, the concentrations were essentially the same in patients with and without pregnancy-induced hypertension (Table II).

We cannot fully explain this conflict between our data and those of Entman et al.[6] Most of our patients were followed up closely in prenatal clinics and we readily admitted patients who were showing early signs of pregnancy-induced hypertension. Perhaps a difference in the severity and duration of disease is in part responsible for these discrepant findings. In addition, it is possible that the prepregnancy iron stores were different in patients in the two studies, accounting for part of this difference. We did confirm a poor correlation between serum iron and serum ferritin concentrations.

Volume contraction is seen quite frequently in patients with severe pregnancy-induced hypertension.[7, 8] Goodlin et al.[9] have shown that the ratio of blood urea nitrogen:creatinine is an indicator of intravascular volume contraction. We chose both this parameter and hemoglobin concentration as indicators of hemoconcentration to assess whether this phenomenon could account for the increase in serum iron seen in pregnancy-induced hypertension. Six patients with pregnancy-induced hypertension and three control patients exhibited intravascular volume contraction as reflected by a blood urea nitrogen:creatinine ratio >15. Linear regression did not show a significant correlation between parameters of volume contraction and serum iron concentration in the 30 patients with pregnancy-induced hypertension we studied (Table III). It is likely that volume contraction was suggested in only 20% of our patients with pregnancy-induced hypertension because most were diagnosed early in the course of their disease. In addition, it is possible that the parameters we studied are not so sensitive as more invasive techniques for determining plasma volume. Nonetheless, it does not appear that volume contraction accounts for

a significant portion of the increase in serum iron seen in our patients.

Hemolysis and disseminated intravascular coagulation have long been recognized as complications of severe pregnancy-induced hypertension.[10, 11] They are necessary components of the HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome.[12] Our study demonstrates that mild hemolysis is part of the constellation of signs and symptoms constituting pregnancy-induced hypertension and is not limited to severe disease. Although laboratory evidence of hemolysis correlated well with serum iron levels, these parameters often remained within the normal limits for our clinical laboratory. Therefore, we believe that these laboratory values cannot be used alone to establish a diagnosis of pregnancy-induced hypertension. However, these parameters can be used in conjunction with other clinical and laboratory studies to help with diagnoses in difficult cases.

In summary, our study provides new insight into the pathophysiology of pregnancy-induced hypertension. The elevated serum iron levels observed in many patients with this disorder are derived in large part from hemolysis. The cause of this hemolytic reaction is unknown. It may be caused by physical destruction of red blood cells as a result of intense vasospasm or abnormal endothelial cell–erythrocyte interactions. Conversely, it may be due to immune destruction of red blood cells. The cause of this hemolysis and the role it plays in the pathogenesis and clinical expression of pregnancy-induced hypertension require further investigation.

The effects of long- and short-term maternal caffeine ingestion on human fetal breathing and body movements in term gestations

Jack McGowan, M.D., Lawrence D. Devoe, M.D., Nancy Searle, B.A., and Roy Altman, Ph.D.

Augusta, Georgia

The possible effects of long- and short-term maternal ingestion of caffeine during normal human pregnancy on the breathing and body movements of third-trimester fetuses were studied in 14 patients, selected by a dietary questionnaire, and divided into two equal groups: high consumers (>500 mg/day) (group 1) and low consumers (<250 mg/day) (group 2). All mothers followed a standard study protocol and underwent overnight fasting; studies began with a 30-minute control period, followed by oral administration of 200 mg caffeine, and a 180-minute subsequent observation period with continued maternal fasting. Blood samples for glucose and caffeine were obtained every 30 minutes and continuous recording of fetal breathing and body movements were entered on a microcomputer for off-line analysis. The two groups were similar for all obstetric outcome features. Plasma glucose levels were similar and constant in both groups whereas caffeine levels increased significantly at 60 minutes after administration; mean plasma caffeine levels were significantly higher in group 1 than in group 2 at all intervals. Fetal breathing rates and body movement incidences were similar in both groups before and after caffeine administration. Fetal breathing movement incidence decreased significantly in group 2 but was sustained at baseline levels in group 1 throughout the study. High long-term ingestion of caffeine during pregnancy is associated with higher maternal plasma caffeine levels and fetal breathing activity when compared with low caffeine ingestion. Short-term administration of 200 mg caffeine does not appear to have a significant physiologic impact on these activities. (AM J OBSTET GYNECOL 1987;157:726-9.)

Key words: Caffeine, fetal breathing and body movements, term gestation

Caffeine, a central nervous system stimulant, is consumed by an estimated 95% of American women during their pregnancies.[1] Although its metabolism and physiologic effects have been extensively studied in mothers and infants, little is known about its effects on the human fetus. Maternal caffeine clearance decreases near term.[2,3] Caffeine and theophylline, a caffeine precursor, are rapidly transferred across the placenta[4] and alter both sleep states and cardiorespiratory activity parameters in neonates.[5,6] Both drugs have been used clinically in the treatment of prematurity-related apnea.[7,8] Direct infusion of caffeine in chronic lamb preparations have shown a transient but significant increase in fetal breathing activity.[9] These observations led us to perform the present study to determine (1) whether differences in long-term levels of caffeine consumption during human pregnancy resulted in observable differences in fetal breathing or body movements; and (2) whether short-term administration of oral caffeine to normal pregnant women had a physiologic impact on these fetal activities.

Material and methods

Fourteen normal pregnant women in the third trimester of pregnancy were enrolled from the Obstetrical Clinic of the Medical College of Georgia. After informed consent was obtained to participate in a study protocol, approved by the institutional Human Assurance Committee, a detailed dietary history for the current pregnancy was obtained and the patients were then classified into either a high (>500 mg/day) caffeine-consuming group (group 1) or a low (<250 mg/day) group (group 2). All patients had normal prenatal courses, well-established gestational dates by menstrual history and ultrasound mensuration, normal responses to glucose-loading tests, and singleton fetuses that were normal for gestational age.

Before each study, a period of fasting was begun at 10:00 PM of the preceding evening. Patients came to the fetal study unit at 8:00 AM the next day. After the patient was placed in bed in a semi-Fowler position with

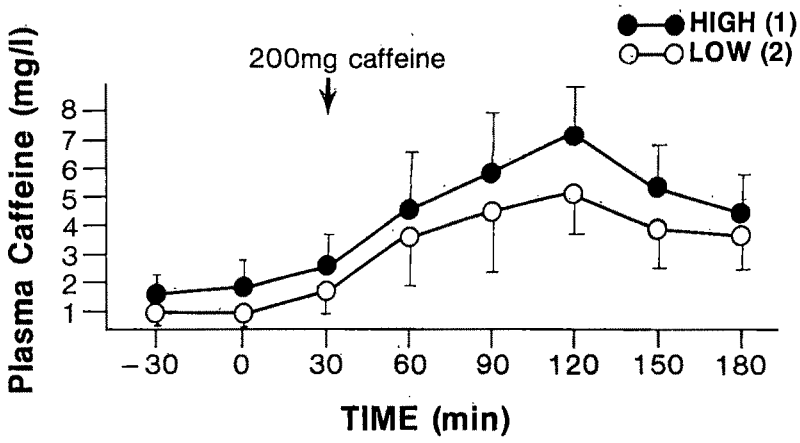

Fig. 1. Mean maternal serum caffeine levels for high caffeine consumers *(closed circles)* and low caffeine consumers *(open circles)*. *Bars* represent standard deviations.

a slight lateral hip displacement, a heparin-lock intravenous catheter was placed in a peripheral arm vein. Blood samples for blood glucose and caffeine levels were obtained at the beginning of each study and at 30-minute intervals until its conclusion 210 minutes later. These samples were divided with blood glucose determined by means of a BG Accuchek analyzer (Bochinger Mannheim Diagnostics, Inc.) and serum caffeine determined after mobile phase solution preparation, processing the extracted serum on reverse-phase column with a Beckman Solvent Delivery 421 module with a 160 absorbance detector and a Hewlett-Packard 3390 integrator.

Studies began with the placement of an ultrasound transducer (ATL 4000/L) on the mother's abdomen, aligned with a sagittal view of the fetal thorax and abdomen. Three observers, two of whom were ignorant of the patient's dietary history, participated in fetal observations. The order of observer participation varied randomly with each study. Fetal breathing movements were defined as the paradoxical movements of the thorax and abdomen about the xiphoid, apnea as the absence of breathing or body movements for more than 6 seconds, and body movements as axial displacement sufficient to obscure fetal breathing movements. Breathing and body movements were entered on-line, via an event marker, to an IBM X/T microcomputer, 384k RAM, with a previously validated software program[10] for acquisition and analysis. Maternal fasting was maintained throughout each study period, and at 30 minutes of observation, each mother was given an oral dose of 200 mg caffeine, with continued observation of the fetus for 180 minutes. This dose of caffeine is equivalent to two cups of regular coffee and is the lowest at which sleep disturbances have been observed in adults.[11]

Data analyzed included mean blood glucose and serum caffeine levels, mean time spent in breathing and body movements, mean breath rate, fail time, gestational age at testing and delivery, fetal weight, and 5-minute Apgar scores. Statistical comparisons used paired *t* tests or analysis of variance with repeated measures, as indicated in the text or tables.

Table I. Obstetric data for study patients

	Group 1 (n = 7)	*Group 2 (n = 7)*
Gestational age at study (wk)	38.0 ± 0.0	37.5 ± 1.8
Gestational age at delivery (wk)	40.5 ± 1.1	39.9 ± 1.0
Birth weight (gm)	3412 ± 369	3342 ± 339
5-min Apgar score	9.1 ± 0.9	9.0 ± 0.8

Results expressed as mean ± SD.

Results

Obstetric data and pregnancy outcome. The group means and standard deviations for gestational age at the time of study and delivery, birth weight, and 5-minute Apgar score are presented in Table I. There were no significant differences between the groups for any of these factors. All infants were born in good condition, were appropriate for gestational age, and without significant anomalies. No mothers had any peripartum complications.

Maternal blood glucose and serum caffeine levels. From the results of the maternal dietary questionnaire, group 1 had a significantly higher mean daily intake of caffeine (863 ± 294 mg/day [mean ± standard deviation]) than group 2 (100 ± 42 mg/day) ($p < 0.001$, *t* test). Fig. 1 illustrates the course of mean maternal serum caffeine levels. Group 1 began at and maintained significantly higher serum caffeine levels than group 2

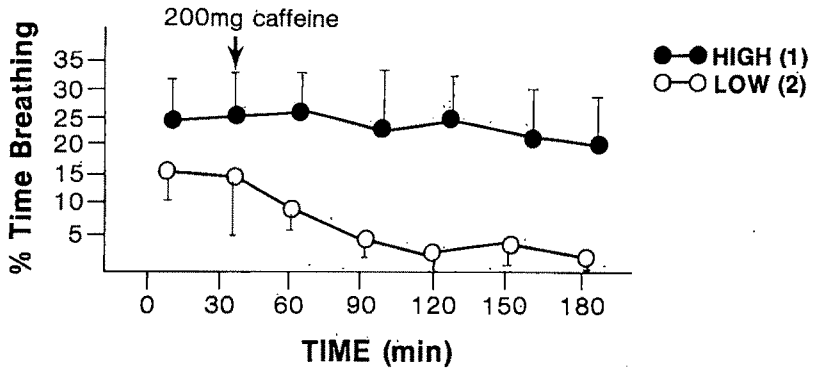

Fig. 2. Mean percentage of time spent in fetal breathing activity for high caffeine consumers *(closed circles)* and low caffeine consumers *(open circles)*. *Bars* represent standard deviations.

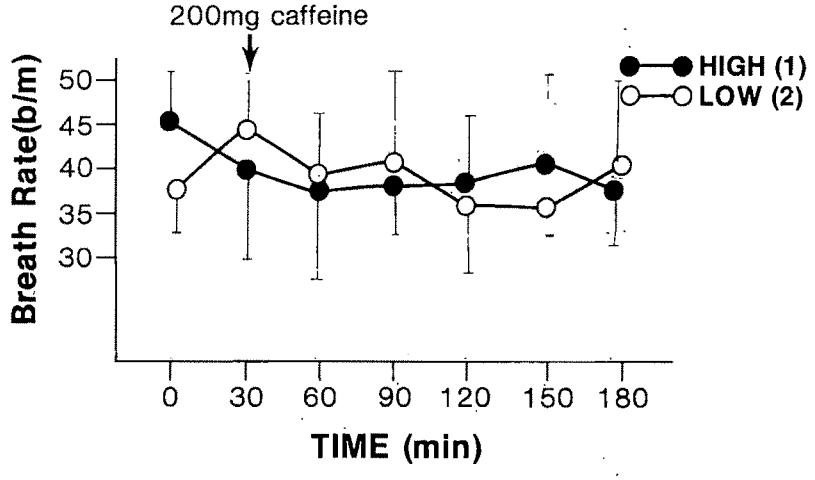

Fig. 3. Mean 30-minute fetal breathing rates for high caffeine consumers *(closed circles)* and low caffeine consumers *(open circles)*. *Bars* represent standard deviations.

at all study intervals. Serum caffeine peaked in both groups at 60 minutes after maternal administration of the 200 mg loading dose and remained significantly higher than baseline values for the remainder of the studies. Mean maternal blood glucose levels (not illustrated) were 78.5 ± 2.5 (SD) mg/dl and 80 ± 2.1 (SD) mg/dl for groups 1 and 2, respectively, and did not vary significantly throughout the observation period.

Fetal breathing activity. Figs. 2 and 3 show mean 30-minute percentages of time spent in breathing and breath rates, respectively, for groups 1 and 2. Although neither group had a significant increase in percentage of time spent breathing, after maternal caffeine administration, the mean 30-minute breathing activity was significantly greater ($p < 0.01$, repeated measures of variance) in the high caffeine-consuming group 60 minutes after caffeine loading and remained so throughout the studies. Mean 30-minute breathing rates were similar for both groups during the studies and did not change significantly from baseline levels.

Fetal body movements. Fig. 4 shows the percentage of time spent in body movements for groups 1 and 2. Although there was a significant decline in body movement activity 90 minutes after caffeine loading in both groups ($p < 0.01$, paired t test), there was no significant trend with time in either group when compared with baseline values, which were similar between the groups.

Comment

Caffeine has been shown to stimulate respiration in premature infants[6] and alters their time spent in rapid-eye-movement sleep.[5] The limited animal data available suggest that bolus administration of caffeine directly to chronically instrumented fetuses results in an abrupt and significant increase in fetal breathing activity.[9] Our present study was an initial attempt to determine both the potential long- and short-term effects on fetal breathing activity associated with maternal caffeine ingestion and thus has no previous human fetal observations with which to compare its findings.

Insufficient numbers of paired maternal and fetal blood samples were available to determine their correlation or whether they were significantly higher for infants of mothers who were high caffeine consumers

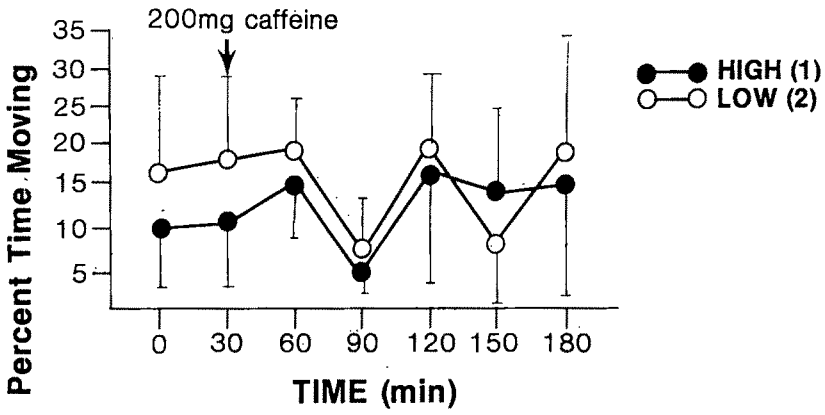

Fig. 4. Mean percentage of time spent in fetal body movement for high caffeine consumers *(closed circles)* and low caffeine consumers *(open circles)*. *Bars* represent standard deviations.

(group 1). However, previous reports suggest that this is quite likely due to the delayed maternal and fetal clearance of caffeine near term.[2, 12] The mechanism by which caffeine exerts its effect on respiratory regulation is still uncertain, although it has been postulated that it enhances respiratory center sensitivity to carbon dioxide,[13] a potent stimulator of in utero breathing activity.[14] The fetal breathing movement percentages, observed in cases where high maternal consumption of caffeine had been present during pregnancy, are higher than would be expected in a previously studied group of normal fasting patients at term.[15] This, in association with the higher mean serum caffeine levels observed in these mothers at the start of the study period, suggests a possible influence for long-term caffeine ingestion during pregnancy on the long-term modulation of fetal breathing activity. It should be noted as well that the breathing activity patterns of fetuses whose mothers were low consumers of caffeine very closely resembled those of normal fasting patients.[15] The absence of significant changes in time occupied by fetal body movements in either group suggests that, if long-term caffeine ingestion plays a role in fetal developmental physiology, it is a somewhat selective one. The decrease in fetal body movement frequency, noted transiently in both study groups, 90 minutes after acute maternal caffeine ingestion, more likely represents a normal cyclic variation in this activity.

Safe levels of maternal caffeine consumption during pregnancy remain to be established. However, the apparent lack of effect on essential fetal physiologic activities, after maternal administration of 200 mg caffeine and in mothers with a history of low daily intake of caffeine during pregnancy, suggests that such a level of caffeine usage may have little influence on fetal behavior in the third trimester of pregnancy. Further studies would be needed to confirm these observations and to establish whether an upper limit of caffeine intake exists beyond which significant fetal biophysical effects might be consistently present.

Leukocyte esterase activity in human amniotic fluid for the rapid detection of chorioamnionitis

Iffath Abbasi Hoskins, Commander, MC, USNR, Timothy R. B. Johnson, M.D., and Craig A. Winkel, Colonel, MC, USA

Bethesda and Baltimore, Maryland

Chorioamnionitis plays an important role in perinatal morbidity and mortality. Fast and accurate diagnosis poses a major problem. A prospective study was performed to assess the value of positive leukocyte esterase test (Chemstrip 9) for the diagnosis of chorioamnionitis during labor. We evaluated 21 patients with chorioamnionitis in labor at term and used 21 matched control subjects. The sensitivity and specificity of leukocyte esterase activity were compared with those of amniotic fluid cultures, Gram stains, maternal pyrexia and leukocytosis, and fetal tachycardia. The sensitivity in diagnosing chorioamnionitis was 91% and the specificity was 95%. The use of this test strip could provide a rapid, inexpensive screening test for chorioamnionitis. (Am J Obstet Gynecol 1987;157:730-2.)

Key words: Leukocyte esterase, chorioamnionitis

Chorioamnionitis plays a major role in perinatal morbidity and mortality. One of the basic problems in diagnosing chorioamnionitis is the lack of uniformity and accuracy of the criteria on which the diagnosis is made. Microscopic examination of the amniotic fluid for the presence of leukocytes and bacteria is an important part of the evaluation for chorioamnionitis. Neutrophilic leukocytes contain several esterases that are not present in serum, urine, or other body fluids.[1-3] Recently, Chemstrip 9 (Biodynamics Division of Boehring Mannheim Corporation, Indianapolis, Indiana) dipsticks were released for use in the detection of leukocytes. The test strip detects the presence of a leukocyte esterase that catalyzes the hydrolysis of an indoxyl carboxylic acid ester to indoxyl. The indoxyl reacts with a diazonium salt to produce a purple color.[3] The esterase activity measured by the assay does not require intact cells and is not affected by changes in the pH, cell, protein, or bacterial content of the fluid.[1] Limitations of the test include interfering substances such as oxidizing or reducing agents, formalin, and some drugs (cephalexin, gentamicin, nitrofurantoin, and phenpyrazine).

We have recently reported on the reliability of leukocyte esterase screening for the detection of urinary and lower genital tract infections in obstetrics patients.[4] In the present study we assessed the feasibility of rapid screening for the presence of leukocytes in infected amniotic fluid by use of Chemstrip 9 dipsticks to detect leukocyte esterase activity.

Material and methods

After informed consent was obtained, amniotic fluid specimens obtained aseptically were collected via aspiration through intrauterine pressure catheters from 21 patients in labor at term. All patients had required placement of the intrauterine pressure catheter for obstetric indications. Each patient had clinical evidence of chorioamnionitis on the basis of the presence of at least two of the standard clinical criteria used for its diagnosis, for example, maternal pyrexia, leukocytosis, uterine tenderness, or fetal tachycardia. Each patient with intra-amniotic infection was matched with a control patient for gestational age, labor, time from rupture of the membranes to delivery, and time from rupture of the membranes to collection of the amniotic fluid. The initial 10 ml of each sample of aspirated fluid was discarded to avoid possible contamination from vaginal flora. Each amniotic fluid sample was divided into two equal parts, one of which was transported in sterile capped syringes to the laboratory for aerobic and anaerobic cultures and the other of which was used for the various tests mentioned here. On arrival in the laboratory, the fluid was immediately inoculated into Bactec (Johnston Laboratories, Towson, Maryland) aerobic and anaerobic culture bottles in preparation for obtaining the cultures. Leukocyte esterase activity was determined by dipping Chemstrip 9 dipstick in the amniotic fluid for 1 second. The strip was then withdrawn over the specimen cup rim to remove excess fluid and

incubated at room temperature for 1 minute. The color reaction was compared with the color chart, and the results were immediately recorded. The leukocyte esterase results were retrospectively compared with the results of the following parameters: amniotic fluid cultures and Gram stains, maternal leukocytosis and pyrexia, and fetal tachycardia. The sensitivity, specificity, and predictive indices for these parameters were calculated.

A positive leukocyte esterase test was defined as a color reaction consistent with a 1+ reading on the accompanying color chart. Maternal pyrexia was defined as a temperature $\geq 37.8°$ C. Maternal leukocytosis was defined as a white blood cell count $\geq 12{,}000/mm^3$. A positive culture was defined as the presence of $\geq 10^4$ colony-forming units (cfu) of one clearly predominant organism per milliliter. A positive Gram stain was defined as the presence of any bacteria per oil immersion field (magnification $\times 100$). Fetal tachycardia was defined as a heart rate >160 bpm.

Results

Table I represents the summation of the various parameters studied in both the chorioamnionitis and the control groups. In the group with chorioamnionitis, 18 of the 21 patients had positive amniotic fluid cultures with organisms $>10^4$ cfu/ml. A single organism was identified in 15 of these specimens. *Escherichia coli* was the predominant clinical isolate in 60% (nine of 15) followed by *Staphylococcus epidermidis* in 20% (three of 15) and group B streptococci in 20% (three of 15). Three of the 21 patients had positive amniotic fluid cultures with more than one organism identified. One patient had *E. coli* and *S. epidermidis* and two had Enterobacteriaceae with group B streptococci. Thirteen patients demonstrated positive Gram stains. The organisms identified were *E. coli* in seven, *S. epidermidis* in two, and group B streptococci in four of the specimens. Leukocyte esterase activity was positive in 19 of the 21 patients in this group. Eighteen of them also had positive amniotic fluid cultures with organisms $>10^4$ cfu/ml. The remaining patient had a growth of only 10^2 cfu/ml on culture. Thirteen of the 18 patients with positive leukocyte esterase activity also showed evidence of bacteria on Gram stain. However, six of the 13 patients with positive leukocyte esterase activity had negative Gram stains but had varying numbers of white blood cells on the slides. In the control group, the two patients with positive amniotic fluid cultures each grew a single organism (*E. coli* and *Enterobacter aerogenes*). Four patients had positive Gram stains (two with *E. coli* and two with *S. epidermidis*) but none developed signs of infection. One patient in this group had positive test results for leukocyte esterase. She had a positive amniotic fluid culture and a positive Gram stain with *E. coli* as the isolate. She also did not demonstrate clinical evidence of chorioamnionitis.

Table II shows the sensitivity, specificity, and predictive values of the various parameters used in the comparison with leukocyte esterase activity. In our study,

positive leukocyte esterase activity had a 91% sensitivity and a 95% specificity whereas positive amniotic fluid cultures only showed 86% sensitivity and 91% specificity.

Comment

Acute chorioamnionitis usually complicates premature or prolonged rupture of the membranes and remains a potentially lethal infection for mother and baby. Despite the seriousness of this condition, there are major problems associated with its diagnosis. At present it is impossible to determine what constitutes an optimal diagnostic finding. When Smith et al.[5] reviewed the problem of perinatal infection several years ago, they concluded that fever and persistent tachycardia were the main criteria for diagnosing fetal infection. Larsen et al.[6] reported that the presence of polymorphonuclear leukocytes in the amniotic fluid reliably predicted clinical intrauterine infection (presence of polymorphonuclear leukocytes denoting a 100% infection rate), but when a positive bacterial culture was the only finding the infection rate was the same as for patients with neither polymorphonuclear leukocytes nor bacteria. Other reports in the literature show poor correlation of various parameters for the prediction of infection. Listwa et al.[7] studied samples from 95 internally monitored patients and found that the presence of polymorphonuclear leukocytes or bacteria did not predict infection, nor did their absence assure that infection would not occur. Gibbs et al.[8] analyzed amniotic fluid from 35 patients with rupture of the membranes before operative delivery. The presence of more than one polymorphonuclear leukocyte per oil immersion field did not identify those patients at high risk for infection. Thus, for patients suspected to have chorioamnionitis, analysis of amniotic fluid for white blood cells or bacteria seems of little predictive or diagnostic value. These observations are similar to our results where amniotic fluid Gram stains only showed a 62% sensitivity and an 81% specificity and maternal leukocytosis showed a sensitivity and a specificity of 67% and 86%, respectively. Bobitt and Ledger[9] evaluated quantitative amniotic fluid cultures from 28 high-risk laboring patients. Those with colony counts $<10^3$ organisms per milliliter showed no subsequent clinical infection, whereas 56% of the patients with counts $>10^3$ cfu/ml became clinically infected. In our study, amniotic fluid cultures had a sensitivity and specificity of only 86% and 91%, respectively. This may be explained by the fact that the presence of bacteria in amniotic fluid (and their subsequent isolation on culture) does not always correlate with clinical evidence of chorioamnionitis. Also, the sensitivity and specificity of leukocyte esterase activity appear to be superior to those of amniotic fluid cultures for detecting chorioamnionitis because of the limitations of the laboratory facilities that provide the results, specifically in the reporting of positive anaerobic cultures.

Attempts to improve our ability to diagnose intrapartum infection have met with little success. In order to try and identify an optimal screening test for chorioamnionitis, we present our findings in which the use of leukocyte esterase activity allows the detection of infection even in the absence of significant numbers ($>10^4$ cfu/ml) of organisms on culture. Moreover, the use of amniotic fluid cultures is costly and time consuming, whereas leukocyte esterase activity detection is simple, rapid, inexpensive, and easily reproducible. Also, its high sensitivity and specificity suggest that leukocyte esterase–negative amniotic fluid specimens could be eliminated from further testing (for example, cultures and Gram stains). However, the use of this test as a screen to eliminate additional testing or as a preliminary finding on which to base management decisions needs further evaluation in various patient populations and at varying gestational ages.

Changes in cyclic adenosine monophosphate–phosphodiesterase activity in nonpregnant and pregnant human myometrium

Alexander D. Kofinas, M.D., James C. Rose, Ph.D., and Paul J. Meis, M.D.
Winston-Salem, North Carolina

Cyclic adenosine monophosphate–phosphodiesterase is the enzyme responsible for cyclic adenosine monophosphate degradation. We investigated the kinetic behavior of this enzyme in the myometrium of women who were nonpregnant, pregnant at term not in labor, and pregnant at term in active labor. Phosphodiesterase activity was measured in the 100,000 g supernatant by the two-step isotopic procedure. The Km (Michaelis constant) value remains essentially unchanged from the nonpregnant to the pregnant state and subsequent labor in both the low and the high affinity enzymes. During pregnancy the V max (maximum velocity) is 75% less than in the nonpregnant state ($p < 0.005$) and remains unchanged during labor. This is true for both the high and the low affinity enzymes. These changes in the kinetic characteristics of the cyclic adenosine monophosphate–phosphodiesterase are indicative of noncompetitive inhibition. We conclude that this inhibition may be interpreted as part of the mechanism for uterine smooth muscle relaxation and pregnancy maintenance. (Am J Obstet Gynecol 1987;157:733-8.)

Key words: Human myometrium, phosphodiesterase activity, pregnancy

Pregnancy transforms the human uterus from a small, almost solid organ in the nonpregnant state to a large saccular organ with a volume of approximately 5 liters.[1] This dramatic change is characterized by relaxation along with hypertrophy and hyperplasia of the smooth muscle fibers of the uterine wall. Although the contribution of cyclic nucleotides to uterine growth in pregnancy has not been completely determined, increasing evidence suggests that cyclic adenosine monophosphate may play an important role in myometrial relaxation through the effects of this compound on intracellular ionized calcium concentration and myosin light-chain kinase activity.[2, 3] These actions include the following concepts: Cyclic adenosine monophosphate is thought to be the second messenger for β-adrenergic agonists that stimulate adenylate cyclase and induce relaxation. Increasing levels of cyclic adenosine monophosphate promote ionized calcium uptake by the sarcoplasmic reticulum, producing a decrease in cytosolic ionized calcium and thus promote relaxation. Finally, cyclic adenosine monophosphate–mediated phosphorylation of myosin light-chain kinase inhibits this enzyme's activity and promotes smooth muscle relaxation.[4]

Adenylate cyclase catalyzes production of cyclic adenosine monophosphate and phosphodiesterase catalyzes cAMP degradation. For a given production of cyclic adenosine monophosphate, the intracellular levels will depend on the activity of phosphodiesterase. Although phosphodiesterase activity in human myometrium at term has been measured,[5, 6] there have been no studies comparing phosphodiesterase activity from pregnant and nonpregnant human myometrium. This study was undertaken to investigate this matter and to compare the enzymatic activity between samples taken from women in active labor and samples from patients not in labor.

Material and methods

Subjects. Myometrium was obtained from the anterior wall of the uterine corpus of six nonpregnant women who underwent hysterectomy for benign gynecologic indications (adenomatous hyperplasia [two], uterine prolapse [one], endometriosis [two], and adenomyosis [one]). The specimen was obtained immediately after the uterine vessels were ligated. Myometrium was also obtained from uteri of six women not in labor who underwent elective repeat lower segment transverse cesarean section at term and from six women in labor who underwent primary lower segment transverse cesarean section for various obstetric indications (high breech in labor, active labor with maternal herpetic genital lesions, cephalopelvic disproportion, and fetal distress). All nonpregnant patients had an unremarkable medical history and did not receive any medications before hysterectomy. All six patients were operated on while under general anesthesia. All pregnant patients were healthy and their pregnancies were un-

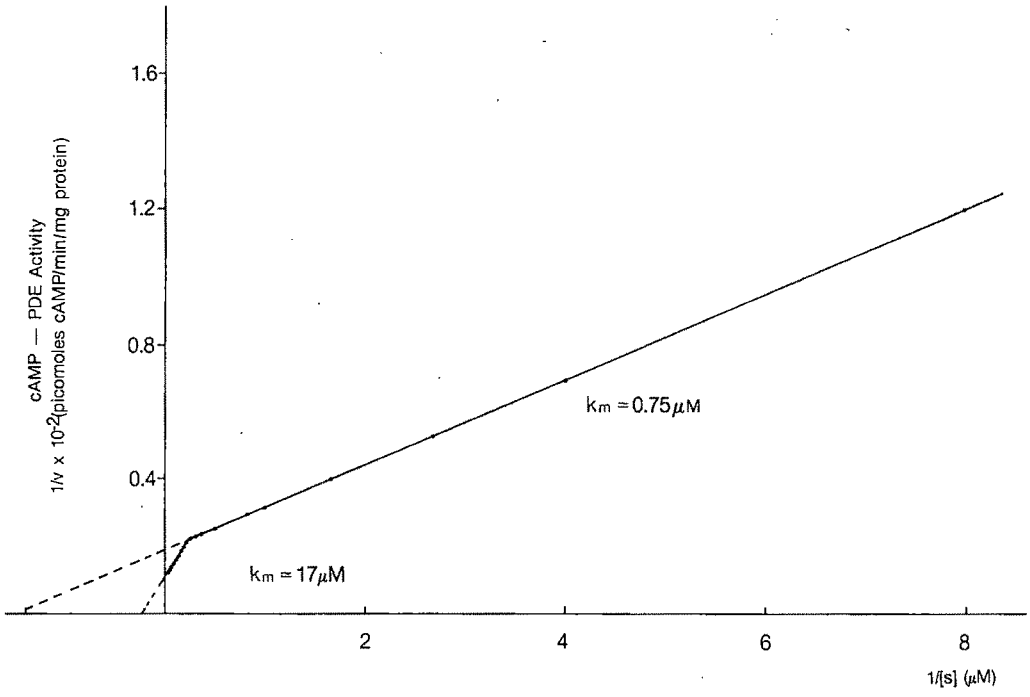

Fig. 1. Representative Lineweaver-Burk plot of human uterine cyclic adenosine monophosphate–phosphodiesterase activity versus substrate concentration. Evidence of two enzymatic forms with apparent Km values of approximately 0.75 and 17 μmol/L correspond to the high and low affinity enzyme, respectively (nonpregnant myometrium).

complicated until the time of delivery. None of the patients received uterotonic agents or other drugs. The procedure was performed with the patients under epidural anesthesia. The study was approved by the Clinical Research Practices Committee and each patient gave informed consent.

Tissue. The tissue biopsy specimen was taken from the upper edge of the transverse uterine incision from pregnant patients and from the lower part of the anterior uterine wall from nonpregnant patients. The tissue was rinsed in saline solution, blotted, and immediately frozen in a dry ice–acetone bath (−65° C). The entire procedure was performed within 60 seconds. Subsequently the tissue was stored at −70° C until assayed.

A 10% (wt/vol) homogenate in 0.25 mol/L sucrose, −10 mmol/L Tris hydrochloride (pH 8) was prepared (homogenization buffer). The frozen tissue was weighed in the frozen state, thawed in a small amount of buffer, and minced. The tissue was then homogenized at 4° C in a Polytron homogenizer for 30 seconds at three fourths of the maximum setting. The homogenate was then centrifuged for 60 minutes at 100,000 g and 4° C. Part of the supernatant was immediately assayed and the rest was stored at −70° C as a 1 : 1 solution in Tris hydrochloride–bovine serum albumin (0.5 mg bovine serum albumin per milliliter of 40 mmol/L Tris hydrochloride, pH 8). It was determined that freezing of the tissue and the homogenate did not change the enzyme activity for up to 6 months. The amount of protein was measured by a rapid and sensitive method that used the principle of protein-dye binding.[7]

Phosphodiesterase activity. Phosphodiesterase activity was measured in the supernatant by the two-step isotopic procedure as described previously by Thompson et al.[8] All assays, conducted in duplicate, were carried out in conditions of linearity with respect to time and protein concentration, allowing measurements of the initial rate of the reaction.

The assay mixture (0.4 ml) contained 5 mmol/L $MgCl_2$, 40 mmol/L Tris hydrochloride (pH 8), 4 mmol/L 2-mercaptoethanol, unlabeled cyclic adenosine monophosphate in different concentrations, labeled tritiated cyclic adenosine monophosphate (containing at least 100,000 cpm), and 0.1 ml of uterine cytosol. Reactions were initiated by the addition of enzyme; incubations were for 10 minutes at 30° C and were terminated by boiling for 45 seconds. After the addition of 0.1 ml of snake venom nucleotidase (1 mg/ml), the mixture was incubated for 10 minutes at 30° C and then placed in an ice bath. The entire content of the tubes was then transferred to Dowex 1-X8 (200 to 400 mesh) columns prepared in Pasteur pipettes (1 ml of 1 : 4 resin slurry was used to make each

column). The tritiated adenosine was then eluted with 2 ml of high-performance liquid chromatography grade methanol. The radioactivity of the eluate was determined in a liquid scintillation counter. In the range of substrate concentration from 0.125×10^{-6} to 100×10^{-6} mol/L, apparent Km (Michaelis constant) and maximum velocity values were calculated by Lineweaver-Burk plots by means of the computer program ENZPACK (Elsevier-BIOSOFT).

Statistical analysis. The differences in Km and maximum velocity values among the different groups were analyzed by one-way analysis of variance and Tukey's least significant difference test. A $\log_{10}$ transformation of the data was carried out to satisfy the prerequisite of homogeneity of variance when analysis of variance was used. A p value of ≤ 0.05 was considered significant.

Results

Kinetic properties of uterine cyclic adenosine monophosphate–phosphodiesterase. Kinetic analysis of cyclic adenosine monophosphate–phosphodiesterase activity versus cyclic adenosine monophosphate concentration by double reciprocal plots according to Lineweaver-Burk revealed nonlinear kinetic behavior suggestive of either multiple enzymatic forms or one form with negative cooperativity (Fig. 1). In nonpregnant myometrium in the range of cyclic adenosine monophosphate concentration from 0.125 to 4 μmol/L, an apparent Km value of 0.752 ± 0.046 μmol/L and maximum velocity of 2328 ± 197 pmol of cyclic adenosine monophosphate/min/mg of protein were obtained corresponding to the high affinity form of enzymatic activity. In the range from 5 to 100 μmol/L an apparent Km value of 17.68 ± 1.57 μmol/L and maximum velocity of 13,255 ± 1006 pmol/min/mg of protein were obtained corresponding to the low affinity form of enzymatic activity (Figs. 2 and 3).

In pregnant myometrium at term but not in labor the corresponding high affinity values were Km of 0.758 ± 0.038 μmol/L and maximum velocity of 604 ± 86 pmol/min/mg of protein. The corresponding low affinity values were Km of 22.31 ± 6.24 μmol/L and maximum velocity of 3570 ± 876 pmol/min/mg of protein (Figs. 2 and 3).

Similarly in pregnant myometrium in labor the high affinity values were Km of 0.674 ± 0.042 μmol/L and maximum velocity of 502 ± 100 pmol/min/mg of protein and the low affinity values, Km of 23.33 ± 4.44 μmol/L and maximum velocity of 2937 ± 464 pmol/min/mg of protein. The differences among the Km values were not significant but the differences in maximum velocity between nonpregnant and both pregnant groups were significant (analysis of variance, $p < 0.005$) (Figs. 2 and 3). These changes are suggestive of noncompetitive inhibition of uterine cyclic adenosine monophosphate–phosphodiesterase during pregnancy (Fig. 4).

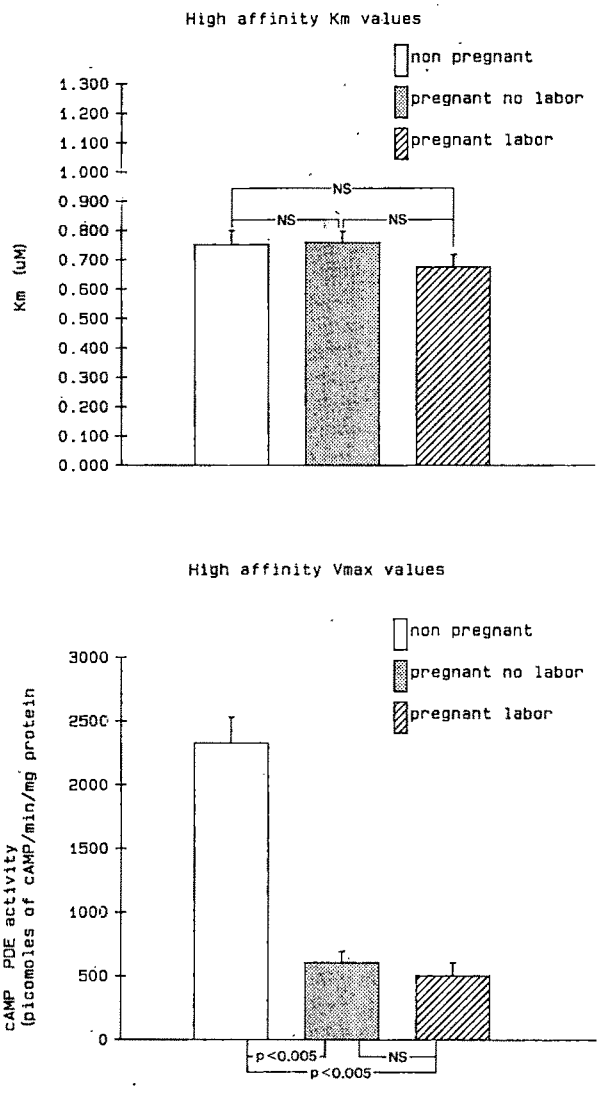

Fig. 2. *Top,* High affinity Km is similar in all three conditions. *Bottom,* High affinity, maximum velocity during pregnancy is approximately 75% less than in the nonpregnant state.

Comment

Normal pregnancy is a unique physiologic phenomenon that provokes major functional and anatomic changes in several organ systems. These changes create an environment necessary for the normal development of the conceptus and its maintenance in utero until maturity is accomplished. Cyclic nucleotides in general and especially cyclic adenosine monophosphate are generally thought to be involved in the control of the important structural and functional changes that occur

Fig. 3. *Top,* Low affinity Km is not significantly different in the three conditions. *Bottom,* Low affinity maximum velocity during pregnancy is also approximately 75% less than in the nonpregnant state.

in the uterus during the course of pregnancy.[2,3,6,9] Since the intracellular levels of cyclic adenosine monophosphate in part depend on the activity of cyclic adenosine monophosphate–phosphodiesterase, our findings suggest that in normal pregnancy a physiologic condition exists that decreases degradation of cyclic adenosine monophosphate, by inhibition of the activity of cyclic adenosine monophosphate–phosphodiesterase, and thus maintains adequate levels of this vital compound.

Although several investigators have examined cyclic adenosine monophosphate–phosphodiesterase activity in different species, few studies exist that have dealt with human myometrial cyclic adenosine monophosphate–phosphodiesterase.[5,10,11] Published studies of human uterine cyclic adenosine monophosphate–phosphodiesterase are contradictory concerning the kinetic characteristics of the enzyme. One group[5] reported the existence of two enzymes with apparent Km values of 12.6 μmol/L for the high affinity and 91 μmol/L for the low affinity enzyme and another group[11] reported the existence of one enzyme with an apparent Km of 1.56 μmol/L. This discrepancy may be related to differences in methodology, a frequent problem in cyclic adenosine monophosphate–phosphodiesterase research and one that makes comparisons difficult. Leroy et al.[6] reported the existence of two enzymatic forms with apparent Km values of 2.8 μmol/L for the high affinity enzyme and 57 μmol/L for the low affinity enzyme. These values are 2.5 times higher than values we report and this can be explained by the different substrate concentrations used. However, their findings are indicative of the existence of two enzymatic forms and are in agreement with our findings. In addition they resolved two peaks of phosphodiesterase activities on diethylaminoethyl cellulose chromatography. Peak I hydrolyzed both cyclic adenosine monophosphate and cyclic guanosine monophosphate and was activated by the ionized calcium–calmodulin complex and peak II was insensitive to ionized calcium–calmodulin and hydrolyzed only cyclic adenosine monophosphate.

Our findings support the existence of two enzymatic forms of cyclic adenosine monophosphate–phosphodiesterase in human myometrial cytosolic preparations and are also in agreement with animal studies in rats, rabbits, sheep, and primates.[2,12-16] The Km value of the high affinity enzyme in our studies remained fairly constant throughout, from the nonpregnant state to term pregnancy and subsequent labor. The low affinity Km value varied slightly but this change was not significant. However, the maximum velocity of both enzymes exhibited a 75% decrease from the nonpregnant to pregnant state. No significant difference exists in both the Km and maximum velocity values between samples from women in labor or not in labor. The lower activity of phosphodiesterase during pregnancy in comparison to the nonpregnant state may increase cyclic adenosine monophosphate levels and thus contribute to myometrial relaxation and pregnancy maintenance.

During active labor the activity of phosphodiesterase was similar to the activity of the enzyme obtained from women not in labor. The study design does not permit any conclusion regarding the significance of cyclic adenosine monophosphate–phosphodiesterase in the initiation of labor. Whether phosphodiesterase activity increases just before or during the early phase of labor and then returns to prelabor levels is a question that might best be examined in an animal model.

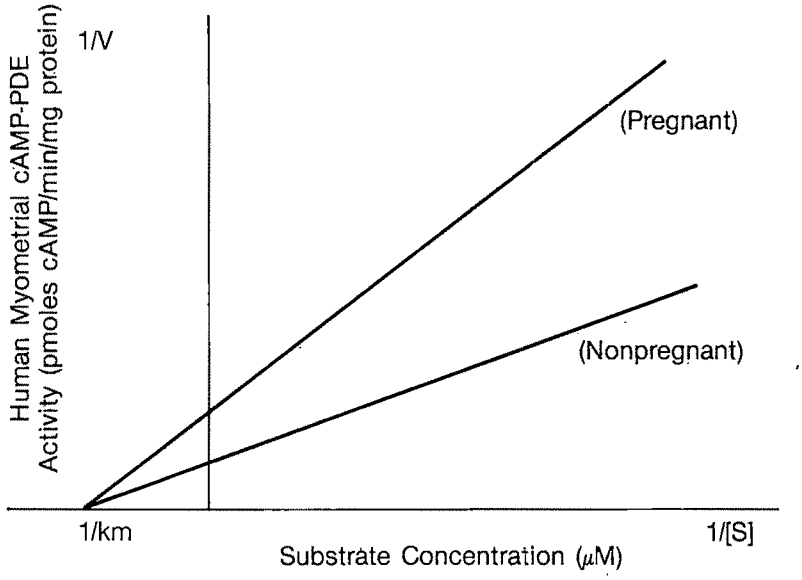

Fig. 4. Noncompetitive inhibition of human myometrial cyclic adenosine monophosphate–phosphodiesterase during pregnancy.

A potential criticism is the fact that the tissue was taken from the lower uterine segment, the least contractile part of the uterus. In one patient (not part of the present data) who underwent lower segment vertical cesarean section with extension to the upper segment, the enzyme activity between upper and lower segment was examined and was not different. In addition, all previous studies in humans examined tissue from the lower segment and this makes the comparisons more meaningful. Berg et al.[11] reported higher phosphodiesterase activity in women treated with terbutaline for preterm labor in comparison to a group of women who were not treated and were not in labor. They concluded that terbutaline was responsible for the increased phosphodiesterase activity, but a comparison between patients in and not in labor may render their conclusion invalid.

Consideration of myometrial phosphodiesterase has potential clinical applications. In the treatment of preterm labor β-agonists are frequently used. However, the use of these potent drugs has been associated with serious cardiopulmonary complications, which are dose related and may be fatal. Several selective phosphodiesterase inhibitors have been developed and are in clinical use as cardiotonic and antiarrhythmic agents.[17, 18] The development of similar selective inhibitors of myometrial phosphodiesterase might help us improve the efficacy of β-mimetic drugs and decrease the dosage required and thus the dose-related complications of these drugs. Conceivably the development of an inhibitor that is specific for myometrial cyclic adenosine monophosphate–phosphodiesterase could eliminate the serious cardiovascular complications associated with increasing levels of cyclic adenosine monophosphate in the myocardium.

In summary, human myometrial cytosol contains two enzymatic forms of cyclic adenosine monophosphate–phosphodiesterase, one low and one high affinity. The Km values, of both enzymes, are similar in the nonpregnant and term pregnant myometrium. However, the maximum velocity of phosphodiesterase in the term pregnant myometrium is 75% less than in the nonpregnant myometrium. Comparison of the enzyme from women in labor with the one from women not in labor did not reveal any differences in both Km and maximum velocity for both enzymatic forms. These findings suggest that cyclic adenosine monophosphate–phosphodiesterase may contribute to myometrial relaxation and pregnancy maintenance.

Pregnancy outcome in medically complicated and uncomplicated patients aged 40 years or older

Deborah K. Lehmann, M.D., and James Chism, M.D.
New Orleans, Louisiana

Patients (183) who were delivered at age ≥40 years were studied to ascertain the nature and frequency of maternal and fetal complications at a single institution in a recent time period. These patients were further grouped into those of low parity, those who began pregnancy without underlying disease, and those who began pregnancy with underlying medical disorders. For the entire group preeclampsia, premature labor, precipitate labor, and malpresentation were significantly more common. The rate of vaginal delivery was substantially decreased, and serious postpartum morbidity was relatively common. The incidence of stillbirth, perinatal mortality, and abnormal birth weight was significantly increased. There were some differences in the nature and frequency of complications encountered among the subgroups, but no subgroup had a complication rate comparable to our general obstetric population. (Am J Obstet Gynecol 1987;157:738-42.)

Key words: Maternal age and pregnancy outcome, maternal and fetal complications

The effects of increasing maternal age on pregnancy outcome remain an unresolved issue for several reasons. Previous reports[1-5] have arrived at discordant conclusions, perhaps because advanced maternal age is associated with many other variables in patient characteristics. The older patients vary with respect to parity and the presence or absence of underlying medical disorders. This group is also socially diverse, with many women delaying childbearing because of professional or personal goals.[6] Conversely, there has been no decrease in the percentage of women delivering at age ≥40 years in our population of medically and economically indigent patients. The present study is an attempt

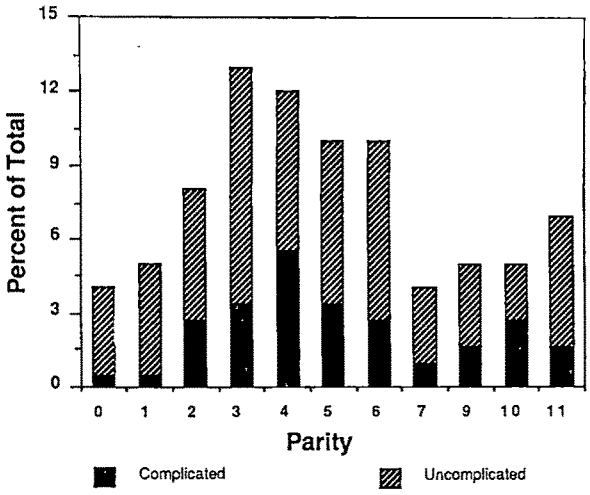

Fig. 2. Bar graph of parity distribution within the study group. Results are given as percentage of entire study group. Patients with medical complications *(solid bars)* are compared with patients without medical complications *(hatched bars)*.

to ascertain the extent of complications encountered in a recent time period. We hypothesized that any increase in complications could be attributed to the presence of medical disorders that antedated the pregnancy or to high parity rather than to advanced maternal age per se.

Material and methods

Delivery logbooks of Charity Hospital at New Orleans from May 1, 1983 through April 30, 1986 were used to identify women who were aged ≥40 years with a gestation of >20 weeks at the time of delivery. The maternal charts were retrieved from medical records; no patient whose chart was complete was excluded for any reason. Of the 196 charts, 183 were obtained and individually reviewed, the data were abstracted onto a predesigned form, any readmission within 42 days was also reviewed to ascertain if a delayed complication had occurred. The patients studied were divided into subgroups on the basis of the presence or absence of medical disorders before the pregnancy; a subgroup of patients of low parity was formed consisting of all patients who were para 2 or fewer at the time of admission for the index delivery. Results were compared with the outcomes recorded in our computerized data base for all patients on the Tulane obstetric service at Charity Hospital. Differences were subjected to statistical analysis with a binomial independent test with significance accepted if $p < 0.05$.

Results

During this time interval there were 9769 deliveries on the Tulane service; the 183 patients aged ≥40 years constituted 1.87% of our obstetric population. The age distribution within the study group was skewed toward the lower range; only 16 of the patients were aged ≥45 years. The average age for the entire study group was 41 years 7 months. Of these patients, 150 were para 3 or more at the time of admission for delivery of the index pregnancy. The distributions of age and parity are given in Figs. 1 and 2. The obstetric complications (Table I) of pregnancy-induced hypertension and abruptio placentae, premature labor, precipitate labor, and malpresentation were all increased. There were only two cases of placenta previa, which is not different from the 0.4% incidence seen in our general obstetric population. The percentage of women who were delivered vaginally (74.3%) was decreased, but the rate of delivery by repeated cesarean section (6.5%) was not increased. Stillbirth and perinatal mortality were abnormally frequent. Of the birth weights, 75% were normal, with 17.5% of the infants weighing <2500 gm and 7.6% of the infants weighing >4000 gm. In comparison, 86% of our entire population of infants weigh between 2500 and 4000 gm at birth. Hemorrhage that required transfusion was seen in 6% of the patients, and there was a trend toward increased febrile morbidity. Deep venous thrombosis, thrombotic pulmonary emboli, or pulmonary edema was seen post partum in eight patients, and seven patients required admission to the intensive care unit.

Fifty patients with an average age of 42 years 3 months had medical disorders that antedated the pregnancy. Of these 50 patients, 37 had hypertension, 15 had diabetes, and 10 had both hypertension and diabetes. The remaining medical disorders included

*p = <0.05.

neuropsychiatric disease, arteriosclerotic heart disease, asthma, tuberculosis, collagen vascular disease, chronic hepatitis, and syphilis. Seven of these patients had more than one underlying problem. The maternal and fetal outcomes for this subgroup are worse than the general population; antepartum complications (Table I) of preeclampsia and premature labor are both elevated as are fetal complications of malpresentation and fetal distress. These women were delivered more often by cesarean section (Table II); 43% of the cesarean sections were done for fetal distress (diagnosed by severe variable or persistent late decelerations), 25% for malpresentation, and 25% for failure to enter labor or obtain normal progress during obstetrically indicated induction of labor. Pulmonary edema, deep venous thrombosis, and pulmonary emboli were seen as postpartum complications (Table III) in 14% of the subgroup with medical disorders and were the cause of admission to the intensive care unit for 10% of this subgroup. Two cases of pulmonary emboli occurred during the second to sixth weeks post partum, which required readmission to the hospital and intensive care.

Patients (133) with an average age of 41 years 7 months did not have underlying medical disorders at the inception of pregnancy. Of these women, 110 were para 3 or more at the time of admission for the index pregnancy; this distribution of parity is equivalent to that of the entire study group. These women experienced less preeclampsia and fetal distress, but premature labor remained significantly elevated, and precipitate labor appeared to be a substantial problem. The route of delivery for these patients is not different from that for the entire obstetric population. The stillbirth rate remains elevated. A birth weight of <2500 gm is not different from the general population, but a birth weight of >4000 gm is more common (Table IV). Twelve percent were noted to have uterine atony or required manual removal of a retained placenta; two thirds of these patients also required a transfusion, which resulted in an elevated rate of transfusion for this subgroup.

Thirty-three patients with an average age of 41 years 1 month were para 2 or less on admission for the index delivery. Of these patients, 70% did not have underlying medical disorders; this distribution is equivalent to that of the entire group. These lower parity patients also had an increased incidence of preeclampsia, malpresentation, and fetal distress. This subgroup had the highest rate (49%) of cesarean sections. Failure to progress accounted for half of the cesarean sections, and the remainder were evenly divided between malpresentation and fetal distress. This group also has a high stillbirth and perinatal mortality rate, but the stillbirths occurred in women with serious underlying medical disorders. There is again a tendency toward an abnormal birth weight, with only 70% of infants weighing between 2500 and 4000 gm. The number of infants who weighed <2500 or >4000 gm in this sample is too

small to reach statistical significance as separate groups. Peripartum hemorrhage that required transfusion occurred in 9% of the patients of lower parity. This is elevated with respect to the general obstetric population and was attributable to placenta previa, abruptio placentae, and one case of uterine atony at cesarean section after a prolonged second stage. The two patients with deep venous thrombosis or pulmonary edema had underlying medical disorders.

Comment

Other studies[7-9] have also noted increases in the complication rates for both mother and baby when maternal age increases. Social position, parity, and the presence or absence of underlying medical disorders must also be considered to affect obstetric outcome. In our study there was no correlation between low or high parity and the presence or absence of preexisting disease. This implies that any difference in outcome between the three subgroups is not attributable to confounding the effects of parity with the general medical health of the patient.

In patients without underlying medical disorders the absence of chronic hypertension appeared to protect them from high rates of preeclampsia. However, their general good health did not protect them from increased rates of other maternal and fetal complications, including stillbirth. These patients delivered heavier infants. Of these patients, 16% were estimated to be <36 weeks when delivered, but only 12% of the infants weighed <2500 gm. The older women were more likely to have hypertension, diabetes, or both than younger patients. As would be expected, the incidence of preeclampsia was elevated in those patients of low parity or with underlying hypertension and was associated with increased rates of prematurity, low birth weight, malpresentation, and fetal distress. The patients of lower parity had high rates of preeclampsia but normal rates of prematurity. They tended to develop preeclampsia that was later in onset and of milder severity than the women with underlying medical disease. Because the onset of disease tended to be later, their rate of prematurity was not as high. The highest cesarean section rate is seen in the subgroup of lower parity, presumably because these women did not have the advantage of previous vaginal deliveries. The 23 women of low parity who had no underlying medical diseases encountered complication rates that appeared similar to the entire group. However, the small numbers preclude statistical certainty that their outcome is comparable. Small statistical advantages to being of low parity and in good general health would be missed with this sample size.

The incidence of premature delivery is elevated in patients with and without medical complications but not in the subgroup of lower parity. Thus the overall ele-

vated prematurity rate appears to be associated with either the presence of underlying medical disorders or with high parity. Other studies[7] have not consistently found an increase in the prematurity rates of older, healthy parous women. Malpresentation is increased in all the subgroups and is not simply a reflection of prematurity or high parity, since it is increased in the subgroup of women of low parity, who do not have an increased prematurity rate. Fetal distress is elevated in the medically complicated subgroup, and the five patients in the low-parity group with the diagnosis of fetal distress all had underlying medical disorders. The observation that birth weight is increased in the group without medical complications, together with the absence of fetal distress, implies that advanced maternal age alone does not impair placental function or fetal growth. The increased rates of stillbirth and perinatal mortality in the medically uncomplicated group are attributable primarily to prematurity but also to abruptio placentae.

As has been noted in other studies,[7, 10, 11] the cesarean section rate is increased in these patients. When patients of low parity with medical complications are excluded, the vaginal delivery rate is equivalent to the general obstetric population. However, 60% of our general obstetric population are primiparas or nulliparas, and their cesarean section rate should be higher than a group of women with this parity distribution. The rate of repeated cesarean sections is not elevated and cannot account for the overall increase in cesarean sections. In our hospital fetal distress and malpresentation are the indication for about 20% of the primary cesarean sections. These two diagnoses were the indication for about 50% of the primary cesarean sections performed in the study group and account for some of the increase in the cesarean section rate. The other major indication for cesarean section was failure to progress in labor. This problem may be attributable to cephalopelvic disproportion associated with increased birth weight or to our inability to always successfully induce normal labor whenever delivery is deemed appropriate for maternal or fetal indications.

We found four patients in the group with medical complications who had deep venous thrombosis, two of whom also had pulmonary emboli. This is equivalent to an incidence of 1:12 for thrombosis and 1:25 for pulmonary emboli. The usual rates for these disorders quoted in the obstetric literature[12] are 1:100 for postpartum deep venous thrombosis and 1:750 for pulmonary emboli. Pulmonary edema and admission to the intensive care unit also appear to be considerably more frequent than usual. Rates for these complications do not appear in the general literature, and we do not have them for our hospital. Although there was no maternal mortality in these 183 patients, serious maternal morbidity was observed. Preeclampsia, complications of cesarean section, obstetric hemorrhage, pulmonary edema, and pulmonary emboli are all frequently quoted[13, 14] as causes of maternal mortality, and we would expect a larger study to validate the elevated maternal mortality associated with advanced maternal age.

In conclusion, we believe that patients considering delivery at age ≥40 years should be advised that there is an increased risk of both maternal and fetal complications. The outcome is more likely to be unfavorable at age ≥40 years, even when the patient is of low parity or in good general health. Those patients of lower parity should expect no reduction in their overall complication rate and can be expected to have a higher rate of cesarean section. There is a further increase in the complication rate for patients with underlying medical disorders; most of this increase is probably attributable to an increased rate of preeclampsia that tends to be severe and relatively early in onset. It seems possible that deliberate alterations in the pattern and content of obstetric care, which take into account these specific complications could have a favorable impact on the maternal and fetal outcome.

Patterns of human fetal heart rate accelerations from 26 weeks to term

Robert Gagnon, M.D.,* Karen Campbell, Ph.D., Cora Hunse, R.N., and John Patrick, M.D.**
London, Ontario, Canada

Computerized analysis of the distribution of 2598 fetal heart rate accelerations in 83 healthy fetuses at 26 to 40 weeks' gestation demonstrated that the currently used definition of an acceleration as ≥15 beats/min for ≥15 seconds is applicable only after 30 weeks' gestational age in fetuses with a basal fetal heart rate of ≤128 beats/min. A significant negative correlation was found between the mean hourly basal fetal heart rate and the mean amplitude of fetal heart rate accelerations from 30 weeks to term. There was also a significant maturational process in the pattern of fetal heart rate and fetal heart rate accelerations that occurred between 26 and 28 and between 30 and 32 weeks; this was characterized by a decrease in basal fetal heart rate, an increase in the amplitude of fetal heart rate accelerations, and an increase in long-term fetal heart rate variability. (AM J OBSTET GYNECOL 1987;157:743-8.)

Key words: Nonstress test; fetal heart rate accelerations during third trimester; effect of gestational age on nonstress test

Antepartum fetal heart rate (FHR) testing, including nonstress and contraction stress testing, has been seriously criticized[1, 2] because of a low positive predictive value, absence of strict and uniform standards for interpretation, and the potential effect of gestational age on FHR reactivity. In addition, until recently accurate recording and interpretation of human FHR with Doppler ultrasound have presented major problems because of a signal loss approaching 60% at 26 to 28 weeks' gestational age.[3] However, signal loss has been markedly reduced by newer autocorrelation-based FHR monitors.[4] In order to provide a better understanding of antepartum FHR testing, the aims of this study were to analyze the distribution of FHR accelerations from 26 weeks' gestational age to term and to examine the influence of the basal FHR on the amplitude of FHR accelerations.

Patients and methods

Patients. Informed consent was obtained from 89 healthy women with pregnancies between 26 and 40 weeks' gestational age. Eighty-three women and fetuses remained in good health, and six were excluded from the study. Five women were delivered of their infants before 37 weeks: Two had abruptio placentae, two had premature labor, and one was delivered of a stillborn infant at 35 weeks (4 weeks after study): All complications were of unknown cause. Another patient was lost to follow-up. The remaining 83 women had normal deliveries at term that confirmed gestational age and the good health of fetuses studied. The average gestational age at delivery was 39.3 ± 0.1 weeks (SEM). The average weight of fetuses was 3350 ± 42 gm. The average 5-minute Apgar score was 9.3 ± 0.1 (mode 9; range 7 to 10). No Apgar score was less than 7 at 5 minutes. Umbilical arterial cord blood samples were obtained at birth in 58 of the 83 fetuses. The mean umbilical arterial P_{O_2} was 17.8 ± 1.0 mm Hg, P_{CO_2} was 50.0 ± 1.3 mm Hg, and pH was 7.27 ± 0.01. Ten (13.7%) women were delivered of their infants by cesarean section: Two developed acute fetal distress in labor (5-minute Apgar scores of 8 and 10, respectively), one had cephalopelvic disproportion, one had a transverse lie at the onset of labor, and six had repeat cesarean sections. Eighty-one fetuses were in vertex presentation and two were breech at the time of delivery.

Experimental design. The women received a standardized 800 kcal breakfast or lunch at 0800 or 1200 hours. All studies began 1 hour later and were conducted in a quiet room with patients either sitting upright in bed or resting in a lateral recumbent position. Women were asked not to smoke for at least 4 hours before studies. Smoking or food intake by patients or observers was not permitted during the study. Women were studied continuously for 1 hour. Nine women participated in more than one study, and these were

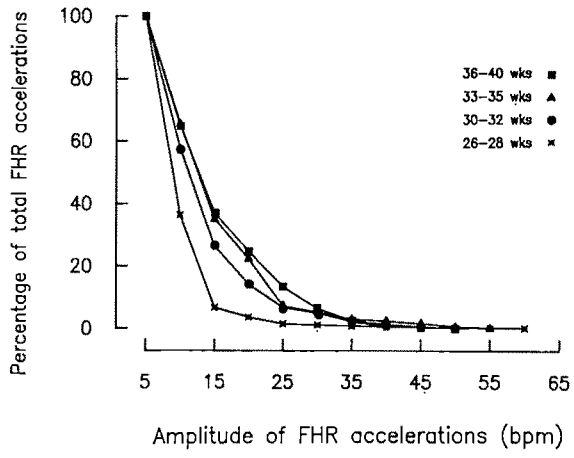

Fig. 1. A cumulative histogram of 2598 FHR accelerations of ≥15 seconds' duration was plotted in successive increments of 5 beats/min to define the distribution of acceleration amplitudes in fetuses from 26 to 40 weeks' gestational age.

conducted in different gestational age groups. Twenty-three studies were done at 26 to 28 weeks, 24 at 30 to 32 weeks, 26 at 33 to 35 weeks, and 28 at 36 to 40 weeks, for a total observation time of 101 hours.

Fetal heart rate measurements. Fetal heart rate was recorded with a Hewlett-Packard 8040A (Hewlett-Packard GMBH, Boeblinger, Federal Republic of Germany) external monitor by use of a compact transducer and was analyzed on-line by a Sage II microprocessor (Sage Computer Technology, Reno, Nevada) as previously described.[5] The FHR intervals were examined by means of an artifact detection algorithm,[6] and valid pulse intervals were averaged over 3.75 seconds. During on-line analysis a baseline was fitted to the heart rate record,[7] and accelerations of ≥10 beats/min for ≥15 seconds above the baseline were recognized automatically.

For each 10-minute interval the basal FHR (beats per minute), the mean minute range (milliseconds),[4] and the number of FHR accelerations were calculated. The mean minute range value was calculated as the difference between the longest and the shortest RR intervals every minute and averaged for the length of observation. The mean minute range is a computer-derived index of long-term FHR variability.[4]

Fetal breathing movements and gross fetal body movements were measured with a real-time ADR ultrasound scanner (Model 2130; Advanced Diagnostic Research Corp., Tempe, Arizona) and will be reported elsewhere.

Data analysis. The basal FHR, the number of FHR accelerations of ≥10 beats/min for ≥15 seconds above the baseline, and amplitude of individual FHR accelerations were determined on line in successive 10-minute intervals. The number of FHR accelerations of ≥15 seconds' duration were also automatically determined off-line for acceleration amplitudes of 5 beats/min and in successive increments of 5 beats/min to a maximum amplitude of 60 beats/min.

Portions of records that could not be analyzed owing to FHR signal loss of more than 30% or patient interruption were not included and made up 5.2% of total study time. The average signal loss of the remaining 96 hours included in this analysis was 6.9% ± 0.9%, 5.3% ± 0.6%, 5.7% ± 0.8%, and 4.5% ± 0.5% at 26 to 28, 30 to 32, 33 to 35, and 36 to 40 weeks', respectively.

Results are presented as grouped means and standard errors of the mean. The significance of differences in the means was examined by Bonferroni t test statistic tables to allow for multiple comparisons.[8] Standard regression analyses with the Pearson product-moment correlations (r) were determined. Regression lines were compared for co-incidence by means of regression procedures described by Kleinbaum and Kupper.[9] This analysis was performed with the package MINITAB (MINITAB Data Analysis Software, State College, Pennsylvania).

Results

Distribution of FHR accelerations. Fig. 1 is a cumulative histogram plot of 2598 FHR accelerations of ≥15 seconds above the baseline in 83 fetuses between 26 and 40 weeks' gestational age. The percentage of total FHR accelerations was calculated in successive increments of 5 beats/min to define the distribution of acceleration amplitudes. Of FHR accelerations between 30 and 40 weeks' gestation, 31.7% were ≥15 beats/min for ≥15 seconds. However, only 6.7% of FHR accelerations were ≥15 beats/min for ≥15 seconds at 26 to 28 weeks.

The percentage of time intervals during which fewer than two FHR accelerations of ≥15 beats/min for ≥15 seconds occurred is plotted in 10-minute increments (Fig. 2, *A*). From 30 to 40 weeks, 57.5% of tracings had fewer than two FHR accelerations at 10 minutes and 2.7% at 60 minutes. However, at 26 to 28 weeks, 95.3% of recordings had fewer than two FHR accelerations at 10 minutes, 67.0% at 40 minutes, and 65.0% at 60 minutes, suggesting that most of the FHR accelerations in this group were <15 beats/min and cannot be detected with an increase in the observation time. However, using a minimum amplitude of 10 beats/min for ≥15 seconds to define an acceleration at 26 to 28 weeks, the length of time from the beginning of recordings until two FHR accelerations occurred was similar to that at 30 to 40 weeks (Fig. 2, *A*).

In Fig. 2, *B*, it can be seen that with a decrease in the minimum amplitude to define an acceleration, there was a concomitant decrease in the percentage of 10-minute intervals during which fewer than two FHR accelerations occurred. This was observed at all gestations from 26 to 40 weeks.

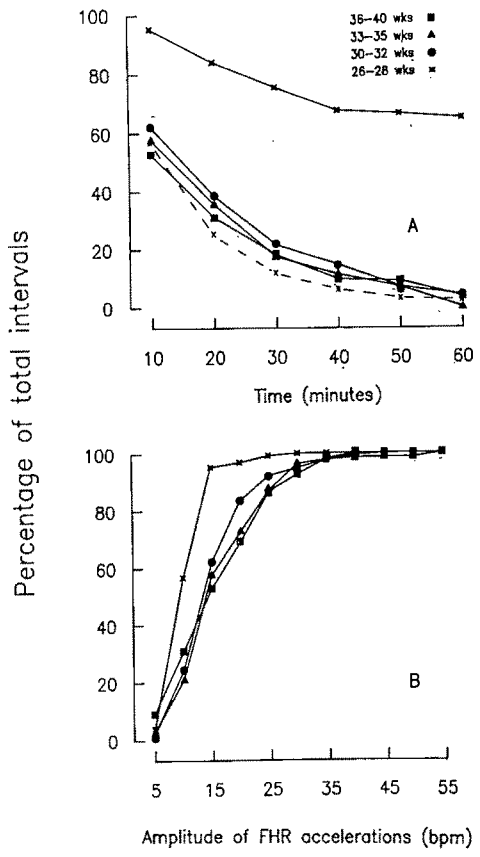

Fig. 2. A, The percentage of time intervals during which fewer than two FHR accelerations of ≥15 beats/min for ≥15 seconds occurred was plotted for all fetuses from 26 weeks to term. The percentage of time intervals during which fewer than two FHR accelerations of ≥10 beats/min for ≥15 seconds was also plotted for fetuses from 26 to 28 weeks on the same time scale (- - - -). **B,** Cumulative percentage of 10-minute intervals during which fewer than two FHR accelerations occurred was plotted in successive increments of 5 beats/min to define the minimum amplitude for an acceleration in all fetuses from 26 to 40 weeks.

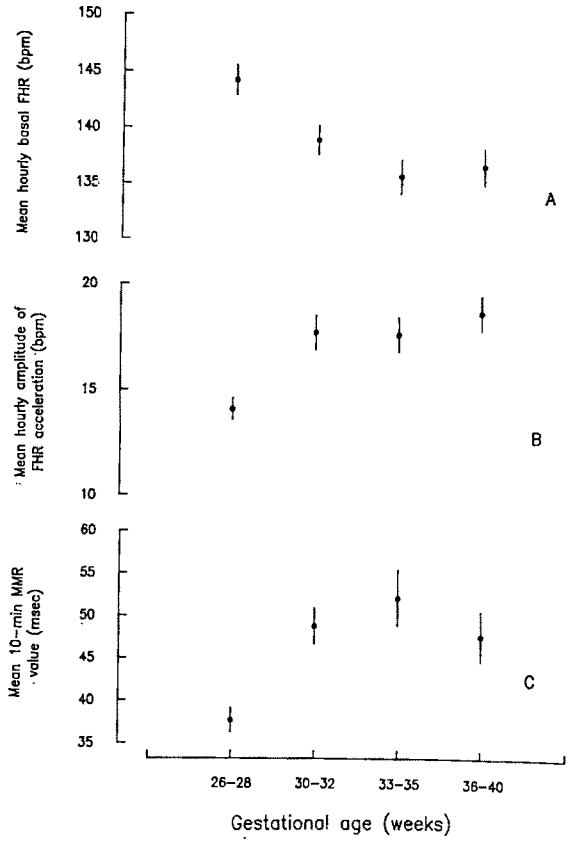

Fig. 3. A, The mean hourly basal FHR (±SEM) was plotted for fetuses at 26 to 28, 30 to 32, 33 to 35, and 36 to 40 weeks' gestation. **B,** The mean hourly amplitude of FHR accelerations and, **C,** the mean 10-minute mean minute range *(MMR)* were also plotted on the same scale.

Relationship between gestational age, basal FHR, and amplitude of FHR accelerations. Mean hourly basal FHR was 144.4 ± 1.3 beats/min at 26 to 28 weeks, which was significantly higher than at 30 to 32, 33 to 35, and 36 to 40 weeks ($p < 0.05$, $p < 0.01$, $p < 0.01$, respectively) (Fig. 3, *A*). Figure 3, *B*, demonstrated that there was a significant increase in the mean amplitude of FHR accelerations from 14.1 ± 0.5 beats/min at 26 to 28 weeks to 17.7 ± 0.8 beats/min at 30 to 32 weeks ($p < 0.01$), and this remained higher at 33 to 35 and 36 to 40 weeks (both $p < 0.01$) (Fig. 3, *B*). Finally, the 10-minute mean minute range was lower at 26 to 28 weeks than at 30 to 32, 33 to 35, and 36 to 40 weeks (all $p < 0.01$) (Fig. 3, *C*). It was important that there was no difference in the mean FHR, acceleration amplitude, and mean minute range between 30 and 40 weeks' gestational age.

There was a significant negative correlation between the mean hourly amplitude of FHR accelerations of ≥10 beats/min for ≥15 seconds and the mean hourly basal FHR at 30 to 32, 33 to 35, and 36 to 40 weeks' gestation (Fig. 4, *B* to *D*), which demonstrated that within individual fetuses at 30 to 40 weeks the higher the mean hourly heart rate, the lower the height of individual FHR acceleration. No such correlation was found at 26 to 28 weeks (Fig. 4, *A*).

A comparison of the regression lines of the relationship of FHR acceleration amplitudes and basal FHR at 30 to 40 weeks, by means of regression procedures described by Kleinbaum and Kupper,[9] confirmed that the regressions of Fig. 4, *B* to *D*, were coincident (slopes and intercepts were equal). Therefore these three sets of data were pooled, and Fig. 5 demonstrated the regression of FHR acceleration amplitude with basal FHR for fetuses at 30 to 40 weeks' gestation. The 95% confidence interval is indicated. It can be seen that a minimum acceleration amplitude of ≥15 beats/min for ≥15 seconds will detect more than 97.5% of FHR accelerations only if the basal FHR is ≤128 beats/min. However, defining the minimum amplitude of FHR as ≥10 beats/min for ≥15 seconds will detect more than

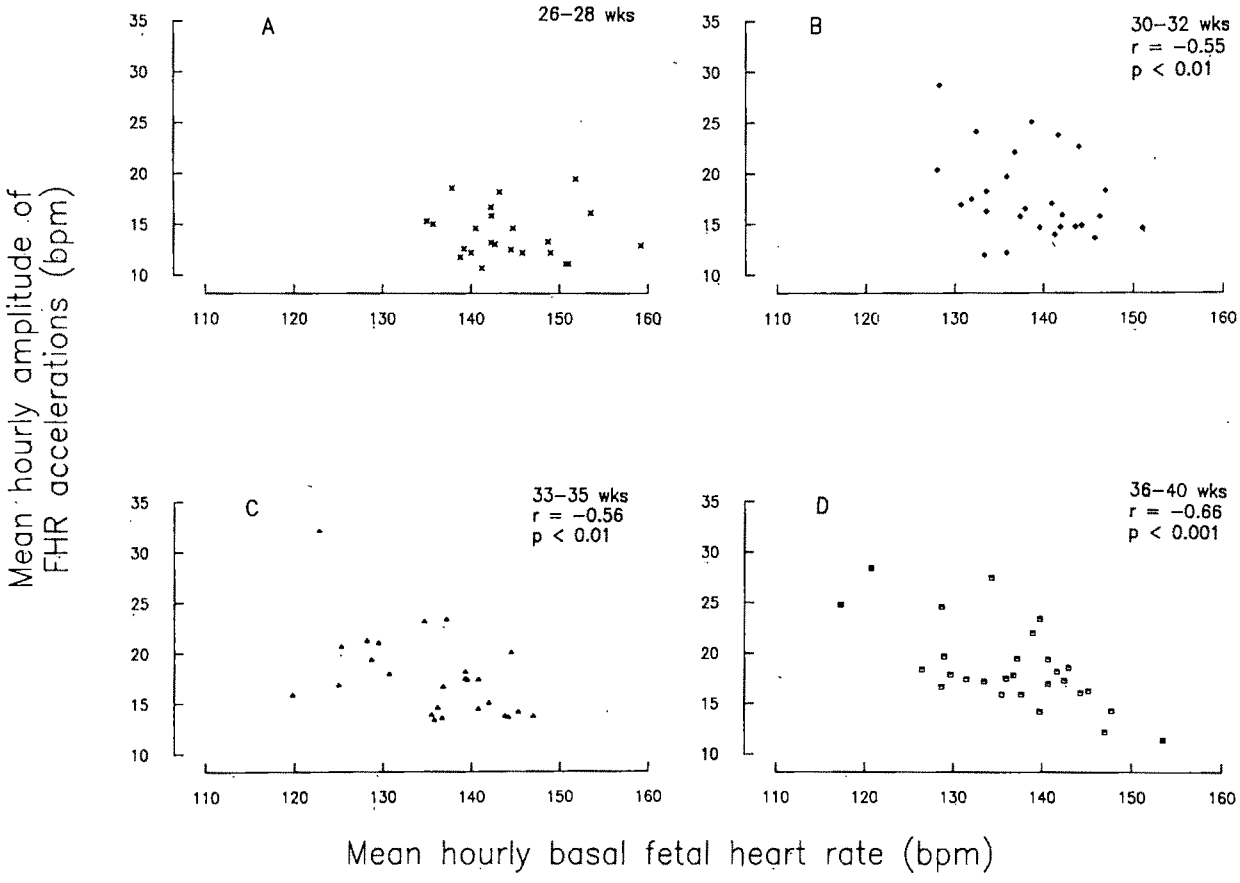

Fig. 4. There was a significant negative correlation between the mean hourly amplitude of FHR accelerations and the mean hourly basal heart rate at all gestations from 30 to 40 weeks **(B, C, D)**. No correlation was found at 26 to 28 weeks' gestation **(A)**.

97.5% of FHR accelerations with a basal FHR of ≤143 beats/min in fetuses of 30 to 40 weeks' gestational age.

Comment

Analysis of the distribution of FHR accelerations in healthy fetuses from 26 to 40 weeks' gestation demonstrated that the currently used definition of an acceleration as ≥15 beats/min for ≥15 seconds is applicable only after 30 weeks' gestational age. Decreasing the minimum amplitude to define an acceleration to 10 beats/min will have two effects on nonstress testing: (1) The length of time necessary to have a reactive nonstress test at 26 to 28 weeks will follow the same pattern as that at 30 to 40 weeks with 15 beats/min as a definition and, (2) there will be an improvement in recognition of FHR accelerations at a basal heart rate of >128 beats/min after 30 weeks' gestation.

The data also demonstrated a maturational process in the pattern of FHR and FHR accelerations that occurred between 28 and 30 weeks and was characterized by: (1) a decrease in basal FHR of 5 beats/min, (2) an increase in the amplitude of FHR accelerations of 4 beats/min, (3) an increase in long-term FHR variability, and (4) the appearance of a significant negative correlation between the mean amplitude of FHR accelerations and the mean basal FHR. It was interesting that no further significant changes occurred in these measurements between 30 weeks and term.

Current literature, between 1974 and 1984, evaluating the predictive value for fetal outcome with the nonstress test has been reviewed by Devoe et al.[1] They reported an average sensitivity of 48%, specificity of 93%, positive predictive value of 38%, and negative predictive value of 95%. A major problem in the methodology of the studies reviewed was the criteria used for test interpretation. There were 21 different definitions for a "reactive" nonstress test in the 44 studies. In addition, the gestational age of fetuses undergoing testing was frequently omitted.[2]

Brown and Patrick[10] increased the length of FHR recording up to 120 minutes using the rationale that two episodes of gross fetal body movements would normally have been predicted during that time.[11] The increase in observation time did not alter the negative predictive value of a reactive test defined as five or more

FHR accelerations of ≥15 beats/min for ≥15 seconds during any 20-minute interval. The present data from healthy fetuses indicated that this is an acceptable strategy for nonstress testing of fetuses from 30 to 40 weeks' gestation, because at 60 minutes only 2.7% of fetuses had fewer than two accelerations of ≥15 beats/min for ≥15 seconds. In contrast, 65.0% of the fetuses at 26 to 28 weeks in this study had fewer than two FHR accelerations of ≥15 beats/min for ≥15 seconds at 60 minutes (Fig. 2, *A*). However, with a definition of ≥10 beats/min for ≥15 seconds for an acceleration in fetuses of 26 to 28 weeks' gestation, only 4.0% had fewer than two FHR accelerations at 60 minutes (Fig. 2, *A*).

Fig. 1 indicated that in fetuses of 26 to 28 weeks' gestation 35.0% of FHR accelerations were ≥10 beats/min for ≥15 seconds, which was similar to 31.7% of FHR accelerations that were ≥15 beats/min for ≥15 seconds at 30 to 40 weeks' gestation. Therefore recognition of FHR accelerations before 30 weeks is only feasible when a minimum amplitude of ≥10 beats/min for ≥15 seconds is used to define an acceleration.

Dawes et al., using an improved method of fitting a baseline to normal human FHR traces,[7] demonstrated a large rise in the numbers of accelerations after 28 weeks.[12] They also reported a significant negative correlation between FHR variation, as expressed as the interquartile range of pulse intervals, and basal heart rate.[12] However, because of the larger scatter in the results the authors suggested that there was no material advantage to be gained by expressing the variability in FHR in terms of the basal FHR.

A previous study of healthy fetuses near term showed that the mean hourly FHR was increased by 18 beats/min over 24-hour periods during times of gross fetal body movements.[13] Further, the mean daily amplitude of FHR was inversely related to the mean daily FHR.[14] Our data confirmed these findings. We also demonstrated that this same relationship was present from 30 weeks to term. This might indicate that individual fetuses after 30 weeks' gestation have a set "gain" for FHR accelerations that is related to the basal heart rate.

Dalton et al.[15] demonstrated in fetal lambs that simultaneous parasympathetic and β-sympathetic blockade reduced heart rate to a greater extent in the younger fetuses. They suggested that there might be a resting cardioacceleratory drive that diminishes with age in fetal lambs. Whether or not this was related to a reduction in catecholamine sensitivity with increasing β-sympathetic dominance during gestation remains speculative. However, this hypothesis could explain the decrease in basal FHR and the increase in long-term FHR variability reported between 26 to 28 and 30 to 32 weeks in this study. It remains to be determined if this reflected a functional maturation of the fetal autonomic nervous system, particularly the predominance of the β-sympathetic system.

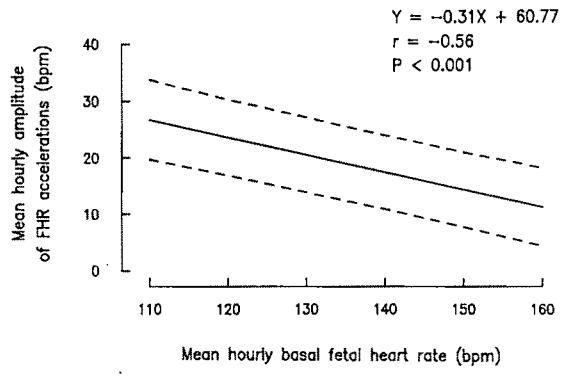

Fig. 5. Regression line (——) of the mean hourly amplitude of FHR accelerations was plotted in relationship to the mean hourly basal heart rate in all fetuses from 30 to 40 weeks with the 95% confidence interval (- - - -). A definition of ≥15 beats/min for ≥15 seconds will detect more than 97.5% of all FHR accelerations only if the basal FHR is ≤128 beats/min.

It is important that previous reports[4, 12, 16] and the current data suggest that the changes in basal FHR, amplitude of FHR accelerations, and long-term FHR variability occur during a critical and narrow period between 28 and 30 weeks' gestational age. Furthermore, no additional significant changes were measured between 30 and 40 weeks' gestational age. This suggests that the autonomic control of FHR in healthy human fetuses might be fully mature by 30 weeks' gestation. Data are not yet available in fetuses of less than 26 weeks' gestation.

Using computerized analysis of FHR we have demonstrated in a group of highly selected healthy fetuses that currently used criteria for nonstress testing are significantly affected by the basal FHR and gestational age. We have used instrumentation that improved heart rate recording but is not available yet for many persons. Twenty-three patients were included in the 26- to 28-week group, which represented a relatively small sample size, but the data suggested that using an amplitude of 10 beats/min to define an acceleration could be a strategy to increase the chance of detecting FHR accelerations before 30 weeks' gestational age. However, this hypothesis should be clinically tested before a new definition for an acceleration is advocated. During the last 10 years there has been a dramatic decrease in neonatal deaths and morbidity in premature newborns of 26 to 28 weeks' gestational age, without any major improvements in use of FHR evaluation of fetal health at this age. Future studies evaluating antepartum FHR testing should also consider the value of adding other FHR information such as baseline heart rate, heart rate variability, and gestational age in order to increase accuracy to predict fetal outcome with nonstress testing.

We thank Professor G. S. Dawes and Mr. Isaac Rapoport for their help with this project and Mrs. H. Cheung and Mrs. T. Clarke for their kind technical assistance.

Riboflavin concentration in maternal and cord blood in human pregnancy

Nancy Wolfert Kirshenbaum, M.D., Joseph Dancis, M.D., Mortimer Levitz, Ph.D., Jean Lehanka, B.S., and Bruce K. Young, M.D.

New York, New York

Riboflavin concentration was measured in sera of a control population and in a series of paired maternal and cord sera. The assay technique was carefully validated and appears to be specific and reproducible. The mean riboflavin concentration in 12 apparently healthy adults was 116 ± 46 nmol/L (SD). In 20 uneventful pregnancies the cord serum concentration was generally higher than the maternal concentration (158 ± 47 nmol/L versus 113 ± 35 nmol/L; p = 0.001). The cord-to-maternal ratio in paired sera averaged 1.45 ± 0.44. There was no detectable difference in binding of riboflavin to cord and maternal serum proteins as measured by equilibrium dialysis (59.0% ± 17% versus 60.8% ± 16%). Comparison of protein binding by paired cord and maternal sera yielded a ratio of 0.99 ± 0.13. The transplacental gradient of riboflavin concentration is unrelated to protein binding and is consistent with active transport by the placenta, as previously demonstrated in vitro. (AM J OBSTET GYNECOL 1987;157:748-52.)

Riboflavin is an essential nutrient that must be delivered to the fetus across the placenta. The human placenta, in vitro, actively transfers riboflavin from the maternal to the fetal circulation, establishing a gradient toward the fetus.[1,2] The situation in vivo is less certain.

The cord serum concentration is higher than the maternal concentration, with a p value of 0.001. Paired maternal and cord sera concentrations show, with few exceptions, a consistent difference that is not evident in protein binding.

*The gradient is the ratio of cord-to-maternal serum riboflavin concentration.

†The relative binding of riboflavin to cord and maternal serum was measured by equilibrium dialysis.

‡Vitamin supplement (3 mg/day riboflavin).

Previous studies of maternal and cord blood concentrations have yielded widely disparate results probably because of differences in analytic technique (Table I).

In the present study the riboflavin concentration was measured in maternal and cord sera at the time of delivery by an analytic technique based on more recently developed methods. High-performance liquid chromatography provides a specificity that was not previously possible, and analytic losses are corrected for by isotope dilution.

Material and methods

Riboflavin assay. The assays are performed in dim light because of the sensitivity of the riboflavin compounds. A blood sample is collected into a dry tube and permitted to clot on ice. It is centrifuged at 3000 rpm for 10 minutes and the serum is collected. The serum is frozen at −70° C until analyzed. Previous studies in our laboratory demonstrated that riboflavin, as identified by high-performance liquid chromatography, remains stable under these conditions for at least 7 months.

To the thawed sample add 0.1 ml ^{14}C-riboflavin (approximately 2500 cpm) to 0.5 ml serum. Radioactivity is measured in triplicate in 50 μl serum. Add 0.6 ml cold trichloroacetic acid, 20%, to the thawed sample and let stand at 0° C for 10 minutes. Centrifuge at 3000 rpm for 10 minutes, collect the supernatant, and neutralize with 0.1 ml 2.4 mol/L K_2HPO_4 buffer, pH 7.0. Inject 0.5 ml supernatant onto high-performance liquid chromatography and fractionate as described below. The eluted fractions are scanned in the fluorometer. The radioactivity (in counts per minute per milliliter) and fluorescence are measured in the riboflavin peak.

Recovery of radioactivity added to high-performance liquid chromatography was consistently >90%. Recovery of radioactivity through the entire analytic procedure varied from 85% to 90%.

Calculations

$$\frac{\text{Eluate (fluorescence)}}{\text{Riboflavin standard (fluorescence)}} \times \text{riboflavin standard (nmol/L)} = \text{eluate concentration (A)} \quad (1)$$

Correction for analytic losses

$$\frac{\text{Serum (cpm/ml)}}{\text{Eluate (cpm/ml)}} \times A = \text{riboflavin concentration (serum + } ^{14}\text{C-riboflavin) (B)} \quad (2)$$

Correction for added ^{14}C-riboflavin

$$B - \frac{\text{serum (cpm/ml)}}{^{14}\text{C-riboflavin (cpm/ml)}} = \text{Riboflavin concentration (nmol/L)} \quad (3)$$

The high-performance liquid chromatographic system has been described previously.[1] In this system, flavin adenine dinucleotide, flavin mononucleotide, and riboflavin elute at approximately 8.3, 9.3, and 10.3 minutes, respectively. Fluorescence is measured on an Aminco-Bowman spectrofluorometer (American Instrument Co., Silver Spring, Maryland) with excitation at 463 nm and emission at 520 nm. Radioactivity is assayed in a Packard Tricarb scintillation counter (Packard Instrument Co., Inc., Downers Grove, Illinois).

Material. Riboflavin, flavin mononucleotide, and flavin adenine dinucleotide were purchased from Sigma Chemical Co. (St. Louis, Mo.). The standard solutions are 26 nmol/L, 19.8 nmol/L, and 3.7 μmol/L, respectively. They are kept shielded from light with aluminum foil at 4° C and are stable for at least 24 hours. ^{14}C-2-D-riboflavin (53 mCi/mmol) was purchased from Amersham (Arlington Heights, Illinois). The purity of the compounds was checked by paper chromatography[1] and high-performance liquid chromatography.

Conversion to lumiflavin. Confirmation of the identity of the riboflavin peak obtained from serum was sought by exposing it to photolysis and comparing its effect to that of similarly exposed authentic riboflavin. The serum and authentic riboflavin were subjected to high-performance liquid chromatography as described above. The riboflavin peak was identified by elution time and fluorescence. This fraction was lyophilized and redissolved in 0.5 ml water and approximately 1000 cpm ^{14}C-riboflavin was added. The specific activity was measured (in counts per minute per milliliter per fluorescence unit). The pH was raised to 8 to 8.5 with 4N KOH. The serum sample and the riboflavin standard were transferred to glass tubes and simultaneously exposed to a 150 W white light at 18 inches for 2 hours. The tubes were covered to prevent evaporation. The pH was returned to neutral and 0.5 ml of each sample was rechromatographed on high-performance liquid chromatography, and the specific activity of the flavin derivative (elution time, 12.6 minutes) was measured.

Protein binding. Comparative binding of riboflavin by maternal and cord sera was measured by equilibrium dialysis. Paired samples of maternal and cord serum, 0.5 ml of each, were placed in individual dialysis bags and dialyzed together in a beaker against 10 ml Earle's buffered salt solution containing approximately 1000 cpm/ml ^{14}C-riboflavin. The beakers were shaken gently for 5 hours at 37° C in the dark. The concentration of radioactivity in the bags and the medium was determined at the end of incubation and percent binding was calculated.

$$\text{Binding (\%)} = \frac{\text{cpm/ml inside bag} - \text{cpm/ml outside}}{\text{cpm/ml inside}} \times 100$$

Subjects. Laboratory personnel served as control subjects for the determination of blood concentrations. Blood samples were drawn after a 2- to 3-hour fast. Only one subject (J. M. L.) took vitamin supplements.

Twenty mothers with uncomplicated pregnancies were selected for study. Mothers are routinely prescribed a multiple vitamin preparation (Stuartnatal, Stuart Pharmaceuticals, Wilmington, Delaware) at the first prenatal visit that contains a daily amount of 3 mg riboflavin. Five mothers were noncompliant and one patient (Table II, No. 15) discontinued supplementation 1 month before delivery. The remaining patients took vitamin supplements until within 24 hours of delivery. Blood samples were collected at delivery. Cord samples were drawn from double-clamped cord sections. The blood was placed on ice and permitted to clot for 15 minutes. The serum was separated by centrifugation at 3000 rpm for 10 minutes and frozen at −70° C until analysis.

Results

The mean serum concentration of plasma riboflavin in 12 apparently healthy subjects on a freely selected diet was 116 ± 46 nmol/L (SD). Notable was the broad range (48 to 222 nmol/L) without evident symptoms.

Five assays were performed on one serum sample (J. D.) over a period of several weeks. The average SD was 8%. Five additional samples were assayed more than once. In four samples the SD was 10% or less and in the fifth it was 17%.

To further confirm the specificity of the assay, the riboflavin peak obtained by high-performance liquid chromatography of the serum sample was derivatized by photolysis, and its major fluorescent product, lumiflavin, was measured as described in the Methods section. Six sera were studied. Fifty percent plus or minus seven percent of the riboflavin peak was recov-

ered as lumiflavin after repeat high-performance liquid chromatography. In five sera the difference in lumiflavin specific activity between authentic riboflavin and serum riboflavin was 8.6% ± 1.3% and in the sixth it was 20%. By this stringent test, >90% of the material in serum assayed as riboflavin was confirmed as riboflavin.

The plasma concentrations in the mothers at delivery were similar to those in the nonpregnant control population (113 ± 35 nmol/L [SD] versus 116 ± 46 nmol/L), with no significant statistical difference between the two groups. There was no detectable effect of vitamin supplementation in the test series. The plasma concentration in the mothers who had taken supplements was 109 ± 32.4 nmol/L versus 130 ± 51.4 nmol/L in the mothers who had not taken supplements ($p = 0.87$).

The cord plasma concentration was higher than the maternal concentration (158 ± 47 nmol/L [SD] versus 113 ± 35 nmol/L), with a p value <0.001 as determined by the double-tailed Student t test. Examination of paired samples revealed a consistent gradient toward the fetus (18 of 20 samples). The mean gradient was 1.45 ± 0.44. Comparison of maternal vein and umbilical vein levels between vitamin-supplemented and nonsupplemented groups showed insignificant differences in mean level and in the ratio of cord to maternal serum concentrations. The gradient was persistent and not significantly different for the supplemented versus unsupplemented groups. The ratio of the cord to the maternal serum concentration for the supplemented group was 1.54 ± 0.43, and for the unsupplemented group it was 1.23 ± 0.39.

Protein binding of riboflavin by maternal and cord plasma varied independently of the riboflavin concentration. The mean binding by 13 maternal plasmas was 60.8 ± 0.6 whereas that of the cord plasma was 59.0 ± 17. Inspection of the individual paired sera results confirmed the absence of differential binding by maternal and cord sera (Table II).

Comment

Riboflavin, or vitamin B_2, is a water-soluble vitamin. It is an essential cofactor in cellular oxidation. It is present in the body as riboflavin and its related coenzymes flavin adenine dinucleotide and flavin mononucleotide. Riboflavin is necessary for fetal growth and development. In experimental animals, riboflavin deficiency is associated with congenital malformations.[4] Smithells et al.[5] administered a multivitamin preparation, including riboflavin, to pregnant women in a controlled study and found a significantly reduced incidence of neural tube defects in the offspring.

Studies conducted in this laboratory by an in vitro perfusion technique demonstrated that riboflavin is actively transferred across human placenta, establishing a higher concentration in the fetal circulation than in the maternal circulation.[1] The driving force is a very rapid uptake of riboflavin from the maternal circulation.[2]

Several factors in addition to placental performance affect the in vivo concentrations of riboflavin. Prominent among these are the rates of metabolism and excretion of riboflavin by mother and fetus and binding to plasma protein. Therefore, one can not assume from the in vitro studies where these factors were not operative that a similar gradient would be found in vivo.

Four reports were found in the literature in which maternal and cord blood concentrations were measured. For each investigation a different analytic technique was used, and the results varied over a wide range (Table I). In three reports the cord concentration was higher than the maternal concentration, and in the fourth the reverse was found. It appeared timely to apply some of the newer analytic techniques to this question. High-performance liquid chromatography was used to isolate riboflavin from other circulating fluorescent compounds. Isotope dilution was used to correct for analytic losses.

A control study was done on a series of 12 adults. The serum riboflavin concentration was 116 ± 46 nmol/L (SD). The range was broad (48 to 143 nmol/L). The concentration was higher than that reported by two previous investigators using high-performance liquid chromatography. Ohkawa et al.[6] studied six subjects and reported a serum riboflavin concentration of 33 ± 2.2 nmol/L (SEM). Lambert et al.[7] reported a mean concentration of 25 nmol/L.

The following procedure was undertaken to confirm the specificity of our analytic technique. The riboflavin peak was collected after high-performance liquid chromatography in the standard assay technique, alkalinized, and exposed to light. On rechromatography, the riboflavin peak had disappeared and a new fluorescent peak, presumably lumiflavin, appeared, with an elution time of 12.6 minutes. By comparing the behavior of the serum "riboflavin" to authentic riboflavin, as described in the Methods section, it was concluded that >90% of the serum riboflavin had been identified correctly.

The analytic technique was used to measure the maternal and cord serum concentrations in a series of 20 pregnancies (Table II). The riboflavin concentration in the cord was 158 ± 47 nmol/L (SD) as compared with 113 ± 35 nmol/L in maternal serum, a statistically significant difference ($p = 0.001$). The concentration gradient was confirmed by examining paired maternal and cord sera, the mean gradient being 1.45 ± 0.44. Long-term vitamin supplementation did not affect serum riboflavin levels and did not contribute to the maternal-fetal gradient established by dietary intake alone in this population.

The perfusion studies had demonstrated that human placenta is capable of establishing a gradient of this magnitude. However, it was possible that differential binding of riboflavin to maternal and cord serum protein contributed to this effect. Specific binding of riboflavin to serum proteins has been reported.[3, 8] However, direct measurement of riboflavin binding by maternal and cord sera does not support the hypothesis. In maternal sera, 60.8% ± 16% (SD) of riboflavin was bound compared with 59.0% ± 17% in cord sera. Examination of the results from paired maternal and cord sera was confirmatory. The cord-to-maternal ratio of riboflavin binding was 0.99 ± 0.13 (Table II). It is clear that protein binding does not account for the transplacental gradient.

The mean fetal:maternal concentration ratio in serum in this series (1.45) closely approximates that observed in vitro in perfusion studies,[2] suggesting that similar mechanisms are operative. Synthesis of the in vitro and in vivo observations suggests the following description of the placental transport of riboflavin. Riboflavin is actively extracted from the maternal plasma, concentrated within the placenta, and transferred to the fetal circulation. The rate of transfer to the fetus exceeds the transfer rate in the reverse direction by a margin that satisfies fetal requirements and establishes a gradient.

The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor

Richard E. Besinger, M.D., Alan A. Compton, M.D., and Robert H. Hayashi, M.D.
Ann Arbor, Michigan

The presence or absence of fetal breathing movements may be helpful in differentiating between true and false preterm labor. We attempted to demonstrate the clinical utility of this simple ultrasonic observation in predicting short-term delivery outcome during suspected preterm labor. A total of 50 pregnancies between 26 and 34 weeks' gestation with presumed preterm labor were observed in a prospective manner. During 20 minutes of observation with real-time ultrasound at the time of admission, fetal breathing movements were observed in 33 patients and considered absent in the remaining 17 patients. In those pregnancies with absent fetal breathing movements, true labor with subsequent delivery occurred in 16 patients. Of the 33 pregnancies with fetal breathing movements present, 29 continued for >48 hours. It appears that the absence of fetal breathing movement is a reliable indicator of imminent preterm delivery, irrespective of fetal membrane status ($p < 0.0001$). The observed mean sensitivity and specificity of this phenomenon in predicting short-term delivery outcome are 96.6% ± 3.3% (mean ± SD) and 80.0% ± 8.9%, respectively. A multivariant statistical model based on the frequency of contractions, white blood cell counts, initial cervical examination results, and premature rupture of membranes could successfully predict delivery outcome in 40% to 75% of cases. The addition of fetal breathing movement analysis to the model allowed for the correct prediction of outcome in 90% of the cases. (Am J Obstet Gynecol 1987;157:753-7.)

Key words: Fetal breathing movements, preterm labor, fetal membrane status

Fetal chest wall movements have been the subject of extensive experimentation and contemplation during the past decade since first described in fetal lambs by Dawes et al. in 1972.[1] Initially, Boddy and Dawes[2] reported that fetal breathing movements were present during parturition and that fetal hypoxia was associated with suppression of breathing, whereas intrauterine asphyxia induced gasping movements in the fetus. More recently, multiple investigators have documented that the cessation of fetal breathing movements is a normal physiologic event during term labor.[3-6] This phenomenon may be mediated by a direct effect of rising fetal prostaglandin levels on central fetal respiratory centers.[7-9]

Because an accurate prospective diagnosis of preterm labor can be difficult, any technique that will alert the clinician to true labor would be helpful. Recently in England, Castle and Turnbull[10] have demonstrated that fetal apnea in gestations less than 34 weeks' duration may be helpful in differentiating between true and false preterm labor, and subsequently predicting delivery outcomes. Although some investigators have been unsuccessful in attempts to replicate this observation,[11-13] more recent observations in term and preterm gestations by Boylan et al.[6] have supported this contention. Our prospective clinical study attempts to corroborate these previous findings and demonstrate the clinical utility of this simple ultrasonic observation in predicting preterm delivery outcomes at a university-based perinatal center.

Material and methods

This prospective study involved 50 women with pregnancies between 26 and 34 weeks' gestation admitted to the University of Michigan labor and delivery unit with a presumptive diagnosis of preterm labor. All study participants had demonstrable uterine contractions on external tocographic monitors and/or demonstrable cervical changes before ultrasonic evaluation. Real-time ultrasound examinations by one of the authors (R. E. B.) and other senior obstetric residents were performed at the time of admission, and the presence or absence of fetal breathing movements was recorded for each patient. Fetal breathing movements were considered to be present if characteristic seesaw movements of the fetal chest or abdomen were sustained for at least 20 seconds. Fetal breathing movements were considered to be absent if no such fetal activity was noted during the 20-minute observation period. Most of these examinations were performed with a General Electric model RT-3000 real-time ultrasound unit.

The observer recorded the following data at the time of admission: presence or absence of fetal breathing

Table I. Association of fetal breathing with delivery outcome (n = 50)

	Delivery interval >48 hr	*Delivery interval <48 hr*
Fetal breathing movements		
Present	29	4
Absent	1	16

movements, biparietal diameter, femur length, presentation, glucose infusion, initial cervical examination results, duration of scan, frequency and strength of contractions, quality of examination, and presence of premature rupture of the membranes. A total of 10 patients had premature rupture of the membranes at the time of admission. The patient's subsequent clinical management was left to the discretion of the involved obstetric staff. Decisions to institute tocolysis, perform amniocentesis, administer antibiotics, or perform a cesarean delivery for progressive preterm labor and other obstetric indications were made on an individual basis.

The interval to delivery was recorded during a chart review. Data obtained from chart review included method of delivery, birth weight, Apgar scores, antibiotic use, tocolysis with ritodrine and/or magnesium sulfate, estimated fetal weight, smoking history, drug history, cervical cultures, white blood cell count, fetal heart rate, glucocorticoids, maternal age, parity, amniocentesis results, and any subsequent clinical diagnosis of chorioamnionitis or abruptio placentae.

Several statistical tests were used in the evaluation of these data. The two-way Fischer exact test was used to evaluate the hypothesis that the presence or absence of fetal breathing movements can predict short-term delivery outcome. The sensitivity and specificity of this diagnostic test were calculated in the standard manner. The χ^2 statistic and two-sample t tests were used to analyze the influence of various clinical parameters on the predictive value of fetal breathing movements. A model system to predict delivery outcome with and without the use of fetal breathing movement data was developed through the use of multivariant discriminate analysis.

Results

The relationship between the presence or absence of fetal breathing movements and imminent delivery in this study of presumed preterm labor is summarized in Table I. Fetal breathing movements were observed in 33 patients at the time of admission and considered absent in the remaining 17 patients. In those pregnancies without fetal breathing movements, true labor with subsequent delivery occurred in 16 patients. Of the 33 pregnancies with fetal breathing movements present, 29 continued for >48 hours. The hypothesis that the presence or absence of fetal breathing movements could successfully predict preterm delivery outcome was supported in 45 of 50 patients ($p < 0.001$). In the absence of premature rupture of membranes (n = 40), this phenomenon was still successful in predicting delivery outcome in preterm labor ($p < 0.0001$).

The mean (±SD) observed sensitivity and specificity of this diagnostic test in the study are 96.7% ± 3.3% and 80.0% ± 8.9%, respectively (Table I). The positive predictive accuracy was 87.9% ± 5.7%, while the negative predictive accuracy was 94.1% ± 5.7%. In the absence of premature rupture of membranes (n = 40), the sensitivity and specificity were 96.3% ± 3.6% and 69.2% ± 11.8%, respectively (Table II).

Our data suggest that several factors may contribute to the ability to observe fetal breathing in this clinical setting (Table III). The duration of scan ($p < 0.02$), white blood cell count ($p < 0.04$), smoking ($p < 0.03$), evidence of premature rupture of membranes ($p < 0.007$), and initial cervical examination results ($p < 0.007$) differed at reasonable levels of statistical confidence between pregnancies with and without fetal breathing movements. There was no statistical difference between the observation of fetal breathing versus fetal apnea in regard to intravenous glucose, frequency of contractions, or use of glucocorticoids. The correlation of premature rupture of membranes and initial cervical dilatation with fetal apnea may represent a potential observer bias in this study.

The correlation of several clinical parameters with a delivery interval of <48 hours confirms what the astute clinician already knows about predicting outcome in preterm labor (Table IV). Frequency of contraction

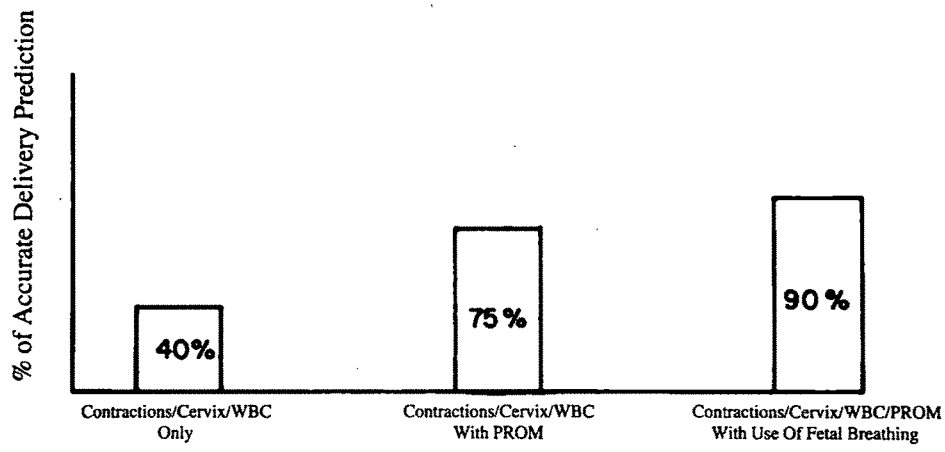

Fig. 1. Predictor of delivery outcome: A statistical model. *WBC* = White blood cell count; *PROM* = premature rupture of membranes.

($p < 0.04$), premature rupture of membranes ($p < 0.003$), initial cervical dilation ($p < 0.0001$), and white blood cell counts ($p < 0.02$) differed significantly at reasonable levels of statistical confidence between both outcome groups. Otherwise, maternal age, parity, gestational age, intravenous hydration, the use of antibiotics, and the method of delivery did not differ significantly in either outcome group. Interestingly, the use of pharmacologic tocolytic agents such as ritodrine and magnesium sulfate did not differ statistically between both outcome groups.

A statistical model was developed from a multivariant analysis of the most important discriminating variables in the prediction of delivery outcome in preterm labor (Fig. 1). Utilizing the clinical knowledge of the frequency of contractions, initial cervical dilatation, and white blood cell counts, the model predicted imminent delivery correctly in only 40% of the cases. Inclusion of premature rupture of membranes data increased diagnostic accuracy in our model to 75%. However, when fetal breathing movement analysis was used in addition to these data, the ability to predict imminent delivery increased to 90%. In the absence of premature rupture of membranes, the ability to predict imminent preterm delivery in this model appears to be dramatically improved with the use of fetal breathing movement analysis. When this model was applied to the diagnostic failures in this study, all five delivery intervals would have been predicted on the basis of simple clinical data without the use of fetal breathing movement analysis.

Comment

The prospective diagnosis of true preterm labor remains a major problem in obstetric practice. Difficulty in diagnosis inevitably results in some patients receiving treatment unnecessarily, with potential serious side effects. Likewise, other patients may not receive the full benefits of aggressive tocolysis unless properly identified as being at risk for preterm delivery. The practicing obstetrician could make use of any new diagnostic techniques that resolve this clinical dilemma.

The use of fetal breathing movements to differentiate prospectively between true and false preterm labor is a novel idea as first proposed by Castle and Turnbull.[10] Cessation of fetal breathing appears to be a normal physiologic event during labor at term[4-6] and during elective oxytocin induction of labor that results in delivery.[3] The notion that fetal apnea occurs during true preterm labor is less concrete. Several investigators have documented this phenomenon during preterm labor,[6, 14] while others have been unsuccessful in replicating this observation.[11-13]

The clinical utility of using the presence or absence of fetal breathing movements to predict imminent preterm delivery is clearly demonstrated in this study. Our data suggest that fetal apnea is a reliable prognostic indicator in preterm labor, with a negative predictive value of 94.1%. It would appear that fetal apnea during threatened preterm labor is a more reliable indicator of delivery outcome than documentation of fetal breathing. With a similar use of tocolytic agents in the two outcome groups, it appears that fetal apnea may still be predictive regardless of subsequent pharmacologic intervention. This indirectly suggests that fetal breathing movement analysis might be useful in identifying those pregnancies at risk to fail tocolytic therapy.

Central nervous system control of fetal breathing movements has been well documented in a variety of animal studies.[15] The phenomenon of fetal apnea during true labor has been attributed to a perceived direct effect of rising prostaglandin levels on central fetal respiratory centers.[15] When prostaglandin inhibitors are given to pregnant lambs, the frequency of fetal breathing movements was significantly increased[7]; similarly, the infusion of prostaglandin E_2 into pregnant lambs

results in the inhibition of fetal breathing.[8] The relationship between fetal breathing movements and prostaglandin levels in humans is poorly documented in humans. However, recent evidence that maternal serum prostaglandin metabolites are predictive of delivery outcome in preterm labor may provide indirect support of these contentions in humans.[16]

The major drawback to any clinical study involving short-term observation of fetal breathing movements is the inadequate sampling of a continuously occurring behavior.[17] Other potential errors include incorrect use of the gain setting, echo alterations by fetal and maternal movements, and poor choice of transducer placement.[17] The diagnostic accuracy of fetal breathing movement detection can be theoretically improved. Maternal inhalation of 3% carbon dioxide and subsequent maternal hypercapnia may increase the incidence of fetal breathing movements and improve our diagnostic accuracy in differentiating between true and false preterm labor.[18] Likewise, maternal glucose infusion may also increase the observed incidence of fetal breathing,[19,20] and thereby decrease the sampling error in the observation of this dynamic phenomenon. The fact that approximately 85% of our patients were receiving an intravenous glucose infusion during the ultrasonic examination may explain our observed accuracy of fetal breathing movement detection during the relatively short 20-minute observation period.

Our statistical model for predicting delivery outcome provides an interesting insight into the clinical dilemma of differentiating between true and false preterm labor. If the clinician uses only traditional data such as initial cervical examination results, white blood counts, frequency of contraction, and premature rupture of membranes to predict delivery outcome, a diagnostic accuracy only of 40% to 75% can be achieved. However, the addition of fetal breathing movement analysis to our model improves the diagnostic accuracy to 90%. Clearly, the additional use of fetal breathing movement analysis in the setting of threatened preterm labor, particularly in the absence of premature rupture of membranes, can be helpful to the clinician.

In conclusion, the use of fetal breathing movements to differentiate prospectively between true and false preterm labor is a novel idea with significant clinical utility for the practicing obstetrician. Although this phenomenon has been well documented in both term and preterm labor, the clinical importance of this noninvasive ultrasonic observation cannot be understated. The reliability and simplicity of fetal breathing movement analysis should allow for its widespread clinical use in the diagnosis and management of preterm labor.

We thank the various senior obstetrical residents who participated in this study, including T. Pelish, T. McGaw, N. Bowdler, W. Beemer, and S. Kiperstock. Statistical analysis was performed with the help of K. Guire from the School of Public Health, University of Michigan.

The significance of one abnormal glucose tolerance test value on adverse outcome in pregnancy

Oded Langer, M.D., Lois Brustman, M.D., Akolisa Anyaegbunam, M.D., and Roger Mazze, Ph.D.

Bronx, New York

A matched control study of 126 women equally divided into three groups (normal oral glucose tolerance test, one abnormal test value, and gestational diabetes mellitus) was undertaken to examine the relationships among oral glucose tolerance test results, glycemic control in pregnancy, and adverse perinatal outcome. Characterization of metabolic control for the one abnormal oral glucose tolerance test value and the gestational diabetes mellitus groups (before treatment) showed no significant difference. After the start of treatment, however, a significant ($p < 0.01$) difference between the groups in level of control was found. While no significant difference in the average birth weight between the three groups was discovered, the incidence of large infants (macrosomia and large for gestational age) was found to be significantly higher in the one abnormal oral glucose tolerance test group when compared with the normal (34% versus 9%; $p < 0.01$) and gestational diabetes mellitus group (34% versus 12%; $p < 0.01$). No significant difference for the incidence of an infant large for gestational age was found between the normal group and the patients with gestational diabetes mellitus after treatment. Neonatal metabolic disorders were found to be significantly higher for the one abnormal oral glucose tolerance test group (15%) when compared with the control and the gestational diabetes mellitus groups (3%). We conclude that, if left untreated, one abnormal value on an oral glucose tolerance test is strongly associated with adverse perinatal outcome. (Am J Obstet Gynecol 1987;157:758-63.)

Key words: Oral glucose tolerance test, gestational diabetes mellitus, metabolic control, perinatal outcome

It has become axiomatic that early diagnosis and treatment of gestational diabetes mellitus provide the best opportunity to prevent perinatal mortality and may provide an opportunity to reduce perinatal morbidity.[1-3] However, controversy has attended attempts to standardize the criteria for carbohydrate tolerance—the means by which gestational diabetes mellitus is diagnosed.[4-6] The best documented and most widely used diagnostic criteria for gestational diabetes mellitus are those of O'Sullivan and Mahan as modified for plasma values by the National Diabetes Data Group (1979) and later adopted by two international workshops,[7-10] which designated gestational diabetes mellitus as a unique entity defined as glucose intolerance with the first recognition or onset during pregnancy. Diagnosis of gestational diabetes mellitus requires at least two values to be abnormal on the oral glucose tolerance test. Evidence for the decision to base the diagnosis on two abnormal values remains unclear. Despite a large number of studies, questions continue to arise as to the efficacy of the current diagnostic criteria. Specifically, the significance of a single abnormal test value during an oral glucose tolerance test as a forecast for perinatal outcome is not defined. We therefore sought to investigate the hypothesis that women with one abnormal oral glucose tolerance test value, when not treated, are at a significantly higher risk for adverse outcome in pregnancy than are matched controls and women diagnosed and treated for gestational diabetes mellitus.

Material and methods

A prospective, matched control study of three groups of women was designed. Group 1 consisted of patients with normal screening and oral glucose tolerance test values; group 2 contained patients with one abnormal test value; and group 3 consisted of patients with gestational diabetes mellitus with two abnormal test values.

Screening and diagnosis. Women were routinely screened between the twenty-fourth and twenty-eighth gestational weeks by use of a 50 gm oral glucose load with venous plasma samples taken at 1 hour. If the

Data are mean ± SD. There were no significant differences between groups for all characteristics except age at testing.
*Body mass index = wt (kg)/ht $(m)^2$.
†Group 1 versus group 3, $p < 0.0001$; group 2 versus group 3, $p < 0.0001$.

results were ≥135 mg/dl, the patient was referred for a 3-hour oral glucose tolerance test. In preparation for the test, all patients were required to consume at least 150 gm carbohydrate for each of 3 days beforehand, with an overnight fast before the morning test. The oral glucose tolerance test consisted of ingesting, within 5 minutes, 100 gm oral glucose load; venous blood samples were drawn before the test and 1, 2, and 3 hours after ingestion. Plasma glucose was measured by Beckman analyzer, with abnormal values defined as follows: fasting, ≥105 mg/dl; 1 hour, ≥190 mg/dl; 2 hours, ≥165 mg/dl; and 3 hours, ≥145 mg/dl.[10]

Ambulatory glycemic control. To determine the ambulatory metabolic control of the subjects, a glucose profile was produced on the basis of self-monitored capillary blood glucose values. Subjects were instructed in the use of a memory-based reflectance meter. Instruction included skills evaluation for obtaining adequate capillary blood sample and testing. At each subsequent visit patients were reevaluated for self-monitoring skills. They were requested to test their blood glucose levels while fasting, before and after eating, and at bedtime. These values were offloaded onto a computer, providing accurate and reliable ambulatory glucose profiles. All group 2 (one abnormal oral glucose tolerance test value) and group 3 (gestational diabetes mellitus) subjects were asked to monitor capillary blood glucose for a 2-week baseline period after the test. For control subjects (group 1), every fourth patient was asked to monitor blood glucose during the baseline period. Patients with gestational diabetes mellitus continued to monitor their blood glucose throughout pregnancy.

Treatment of gestational diabetes mellitus. Diet treatment was calculated by consideration of body mass index before pregnancy. For obese subjects (index >27.3) 25 kcal/kg were prescribed; for normal subjects 30 kcal/kg were prescribed. Insulin treatment consisted of three injections per day divided into fasting (regular and intermediate), predinner (regular), and bedtime (intermediate) doses.

†$p < 0.01$ versus group 1.

Neonatal outcomes. Physiologic measures during this investigation consisted of large for gestational age assessment, macrosomia, and metabolic abnormalities including hypoglycemia (blood glucose <40 mg/dl at birth reconfirmed by venous sample), hyperbilirubinemia (blood level >12 mg/dl), and polycythemia (central venous hematocrit >65%). Large infants were defined as birth weight either ≥4000 gm or ≥90% for a given gestational age.

Analysis. Univariate and bivariate statistical analyses were performed. Categorical data were evaluated with χ^2 analysis and Fisher's exact tests; continuous data were analyzed with Student's *t* test.

Results

Patient characteristics. One hundred twenty-six women were evenly divided between the three study groups. These subjects were drawn from among all women referred for an oral glucose tolerance test in 1985-1986. All groups were matched for race, maternal age, parity, and weight to remove any sampling biases. As shown in Table I, there was a significant difference in gestational week for time of the oral glucose tolerance test when group 1 (normal) and group 2 (one abnormal test value) were compared with group 3 (pa-

*Group 2 versus group 3 in treatment.

tients diagnosed with gestational diabetes mellitus). Although no significant difference existed between groups 1 and 2, the latter were generally tested later. Within the 42 subjects in group 2, the earliest identification of one abnormal test value occurred for five patients during the twenty-ninth gestational week. Six additional patients were identified by 32 weeks' gestation, five more patients were discovered by 34 weeks' gestation, and the remainder were discovered between gestational weeks 35 and 39. Among these subjects, 67% were screened before the oral glucose tolerance test (the remainder were not screened, having been referred directly for the oral glucose tolerance test). Of those screened, 61% were found to have positive test results.

Oral glucose tolerance test profile of glucose metabolism. Characterizing groups 1 and 2 during the oral glucose tolerance test were significantly lower fasting plasma glucose levels than in the patients with gestational diabetes mellitus. Additionally, both 1- and 2-hour values were found to differ significantly between groups 1 and 2 (Table II). For group 2 the pro-

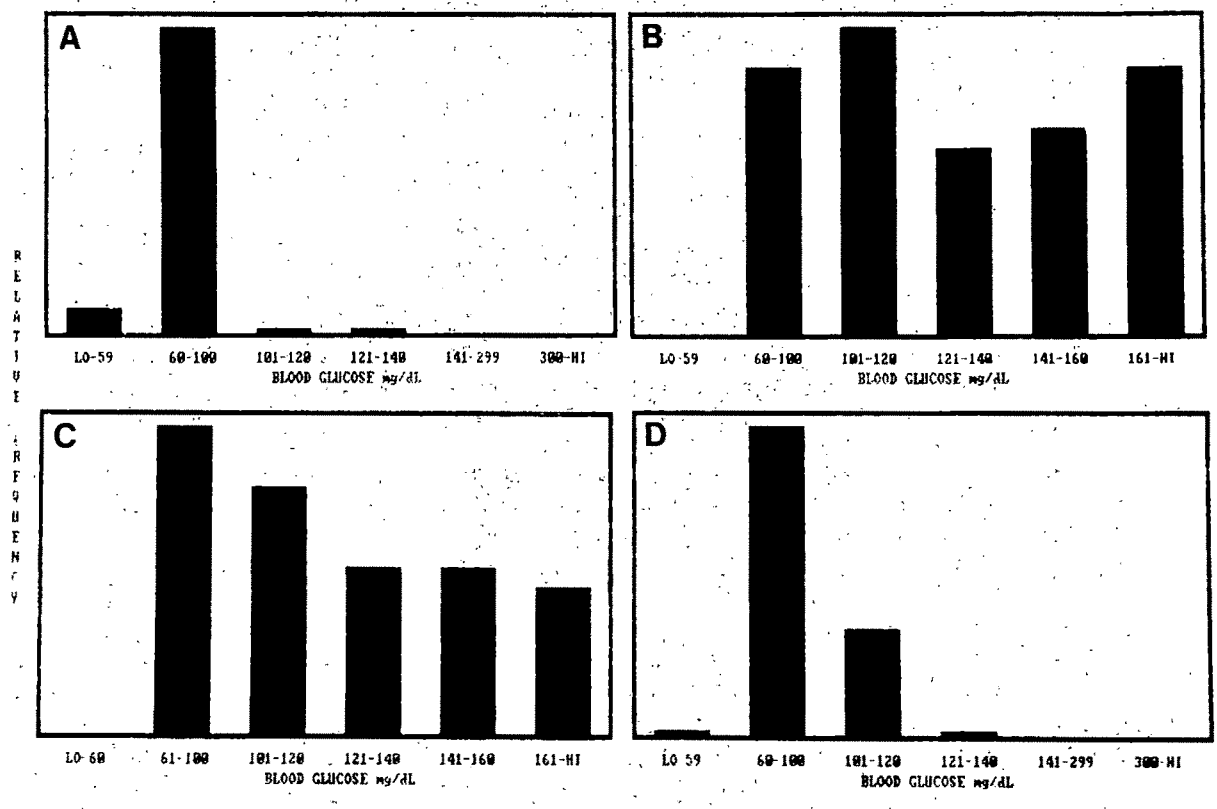

Fig. 2. Frequency distribution of blood glucose values from memory meters corresponding to the ambulatory glucose profiles. *A*, A normal patient. *B*, A patient with gestational diabetes mellitus before treatment. *C*, A patient with one abnormal oral glucose tolerance test value. *D*, A patient with gestational diabetes mellitus who is receiving treatment.

portion of patients with abnormal values favored the 1- and 2-hour periods (5% at fasting, 40% at 1 hour, 48% at 2 hours, 7% at 3 hours).

Ambulatory profile of glucose metabolism. Table III reflects the characterization of metabolic control for groups 2 and 3. Both groups tested their capillary blood glucose with the same frequency, 6.5 ± 1 test per day. A comparison by t test showed no significant difference between groups 2 and 3 before diet or insulin treatment. Within the gestational diabetes mellitus group, 26% were treated with insulin, while the remainder were placed on diet only regimens. No difference in overall metabolic control throughout pregnancy was found between the diet- and insulin-treated subjects. However, a significant difference was uncovered when group 2 patients (one abnormal value) and group 3 patients receiving treatment for gestational diabetes mellitus were compared.

Development of ambulatory glucose profiles. To represent the typical pattern of glycemia for the different groups, we produced ambulatory glucose profiles by use of the memory-based reflectance meter data. This profile represents 2 weeks of self-monitored blood glucose data collapsed into a single typical 24-hour period, represented as three smoothed curves (twenty-fifth, fiftieth, and seventy-fifth percentiles) of glucose values (Fig. 1).[11] There was a significant difference between group 1 *(A)* and both group 3 before treatment *(B)* and group 2 *(C)*. There was no significant difference in terms of average blood glucose and excursions between group 2 *(C)* and group 3 before the start of treatment *(B)*. However, a significant difference was found when the profiles for the group 3 patients treated for gestational diabetes mellitus *(D)* were compared with group 2 *(C)* and group 3 patients before treatment *(B)*. Finally, a comparison of profiles showed no significant difference between group 1 *(A)* and the group 3 patients treated for gestational diabetes mellitus *(D)*. Shown in Fig. 2 are the corresponding glucose values for each ambulatory glucose profile. The profile-derived glucose values for group 2 *(C)* were consistent with the ambulatory profile and reflected the significant difference in the oral glucose tolerance test 1- and 2-hour values when compared with group 1.

Neonatal outcome. No significant differences were found in the average birth weight between the three groups. However, the incidence of large infants (macrosomic and large for gestational age infants) was found

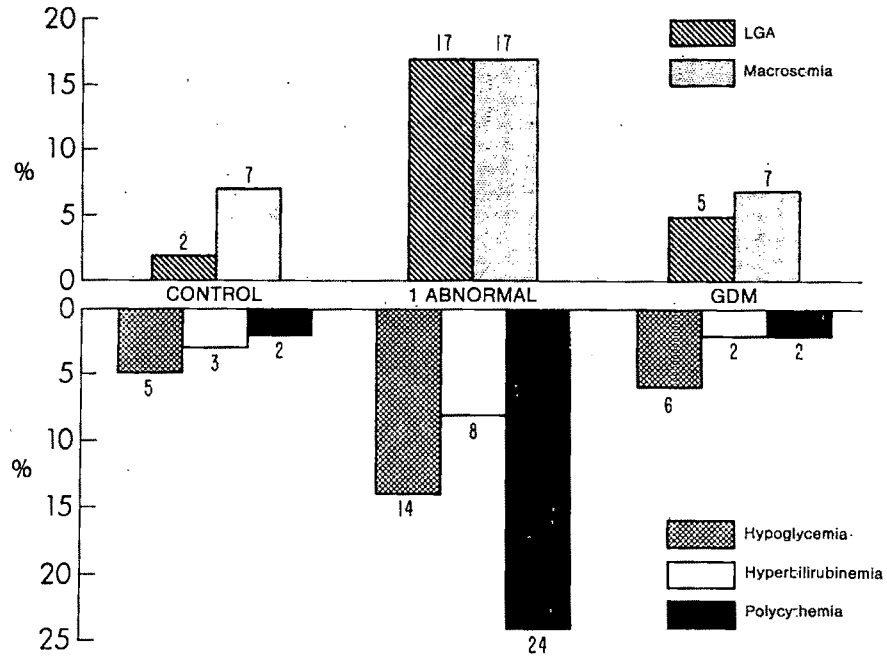

Fig. 3. Neonatal outcome, shown as the relative incidence of adverse neonatal outcomes for the three study groups. The numbers associated with each bar graph represent the actual percentages. *GDM* = Gestational diabetes mellitus.

to be significantly higher in group 2 when compared with groups 1 (34% versus 9%; $p < 0.01$.) and 3 (34% versus 12%; $p < 0.01$; Fig. 3). No significant difference for the incidence of large for gestational age infants was found between groups 1 and 3. Neonatal metabolic disorders were found to be significantly higher for group 2 (15%) when compared with groups 1 and 3 (3%; $p < 0.01$).

Comment

Our data suggest that one abnormal value on an oral glucose tolerance test should be regarded as a pathologic finding. We base this conclusion on three factors. First, we found a striking similarity between the subjects with gestational diabetes mellitus before treatment and those subjects with one abnormal oral glucose tolerance test value when we examined overall glycemic control (as represented by mean and SD). Second, when we used the ambulatory glucose profile as a method of analysis (to avoid the often misleading information from only the mean and standard deviation), we again found that the typical profile produced for gestational diabetes mellitus before treatment was indistinguishable from that of patients with one abnormal test value and significantly different from those for the treated patients with gestational diabetes mellitus. Using the four principal means of characterizing the ambulatory glucose profile (mean, average number of reversals in curve, average excursion after a reversal, and interquartile range), we were able to show that the patterns were both visually and statistically different from those of the treated patients with gestational diabetes mellitus. Third, the incidence of adverse neonatal outcome among the one abnormal test group was significantly higher than for the other groups (specifically, the incidence of large infants and metabolic abnormalities including polycythemia). We believe this high incidence of neonatal metabolic abnormalities was the result of poor glycemic control among the subjects with one abnormal test value. This is supported by previous studies of untreated patients with gestational diabetes mellitus that report an incidence of macrosomia between 20% and 30%,[12-14] a range consistent with the proportion of infants large for gestational age in the one abnormal test group. Therefore, we believe that this group should be considered as identical to group 3 patients who are not treated for gestational diabetes mellitus, with the same risk of adverse perinatal outcome.

Because the patients in the three groups were matched by age, weight, parity, and race, these findings have not been compromised by other factors that have been related to adverse fetal outcome. Furthermore, because our study included women whose one abnormal oral glucose tolerance test value was detected on the average at the thirty-fourth gestational week, these patients did not have undiscovered gestational diabetes mellitus as defined by existing diagnostic criteria.

Controversy still exists as to the criteria for diagnosis of gestational diabetes mellitus in terms of the actual glucose values. Recently, Tallarigo et al.[15] suggested that

even mild hyperglycemia may be associated with adverse outcome in pregnancy. Previously, Carpenter and Coustan[16] proposed stricter criteria for diagnosis of gestational diabetes mellitus. When we examined the 42 subjects in group 2 (one abnormal test value) and used the stricter criteria (95, 180, 155, and 140 mg/dl), 19 subjects would have been diagnosed as having gestational diabetes mellitus and 23 would have been considered normal. However, our analysis revealed that among these 23 "normal" subjects the incidence of adverse outcome was equivalent to that of the group who would have been diagnosed as having gestational diabetes mellitus according to the more strict criteria. Therefore our findings suggest that the criteria for diagnosis of gestational diabetes mellitus need to be modified. Furthermore, if treated, all patients with one abnormal oral glucose tolerance test value would have most probably experienced a significantly lower incidence of adverse perinatal outcome consistent with that found among individuals treated for gestational diabetes mellitus. We therefore conclude that these patients may have had gestational diabetes mellitus, and that the existing screening and diagnostic criteria need to be reexamined in light of these findings.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Ultrasonic ratio of fetal thoracic to abdominal circumference: An association with fetal pulmonary hypoplasia

Anthony Johnson, D.O., Nancy A. Callan, M.D., Vinod K. Bhutani, M.D., Garrett H. C. Colmorgen, M.D., Stuart Weiner, M.D., and Ronald J. Bolognese, M.D.
Philadelphia, Pennsylvania

Real time ultrasound was used in pregnant women who were considered to be at risk for development of pulmonary hypoplasia (n = 26). The population consisted of women who had either premature rupture of membranes (n = 16) or oligohydramnios (n = 10). The ratio calculated by comparing the fetal thoracic circumference to abdominal circumference was obtained in all cases within 10 days of delivery. This ratio correlated strongly with neonatal outcome. Multivariate regression models of neonatal outcome were developed to analyze the relationship of gestational age at which premature membrane rupture occurred, the duration of premature rupture, date of birth, and prenatal diagnosis. The addition of the thoracic circumference to the abdominal circumference ratio increased significantly the proportion of explained variability. Application of this ratio should be considered in evaluating fetal status in oligohydramnios and in the expectant management of premature rupture of membranes. (AM J OBSTET GYNECOL 1987;157:764-9.)

Key words: Pulmonary hypoplasia, premature rupture of membranes, oligohydramnios

The presence of pulmonary hypoplasia has been well documented in both renal and nonrenal origins of decreased amniotic fluid.[1,2] The antepartum diagnosis of developing pulmonary hypoplasia would be beneficial in the management of pregnancies with these complications. Callan et al.[3] have established a normal ultrasonogram for absolute fetal thoracic circumference and for the ratio of thoracic circumference to abdominal circumference. The ratio (thoracic circumference to abdominal circumference) has been reported to remain constant throughout pregnancy (0.94 ± 0.05). An earlier report[4] noted a serial decline in thoracic circumference to abdominal circumference, with the subsequent development of pulmonary hypoplasia.

Our study was done to test the significance of thoracic circumference to abdominal circumference, compared with other parameters in predicting fetal lung growth as manifested by neonatal respiratory function.

Material and methods

The population consisted of patients who experienced premature rupture of membranes at <28 weeks of gestation, duration ≥7 days (n = 16), or patients who experienced oligohydramnios with intact membranes, duration >7 days (n = 10).

Each patient had at least one real time ultrasound examination with a linear array probe (Sonoline SL, Siemens, Erlanen, West Germany; Toshiba SAL 20, Otawara, Japan; Acuson, Palo Alto, California) at 3.5 MHz within 10 days of delivery. The thoracic circumference was measured in the transverse plane of the fetus at the level of the four-chamber view of the heart (Fig. 1). The abdominal circumference was measured in the transverse plane of the fetus at the level of the stomach (Fig. 2). Neonatal assessment was blinded to the ratio of thoracic circumference to abdominal circumference.

Neonatal outcome was assigned to one of four groups on the basis of clinical profile, pulmonary manifestations, and the presence or absence of autopsy, as follows:

Group 1. Neonatal death associated with pulmonary hypoplasia. Neonatal death occurred within 2 days of birth. All these neonates were originally in group 2 until pulmonary hypoplasia was confirmed by autopsy.

Group 2. Clinical diagnosis of pulmonary hypoplasia. There was evidence of respiratory failure and abnormally high pulmonary morbidity in this group. A tentative diagnosis of pulmonary hypoplasia was made on the basis of the following: (a) clinical respiratory disease that did not conform to the classic model of hyaline membrane disease; (b) chest radiographic evidence of small lung volume, with the diaphragm elevated above the seventh rib, downward sloping ribs, and a bell-shaped thoracic cage; (c) ventilatory pressure on inflation of >25 cm water with an alveolar-arterial oxygen gradient of >600 mm Hg; (d)

presence of interstitial pulmonary or pleural air leakage; and (e) any evidence of right-to-left intracardiac shunt.

Group 3. Benign outcome. This group consisted of neonates who experienced transient respiratory failure (<1 day) and whose clinical course was indistinguishable from that of hyaline membrane disease or pneumonia.

Group 4. Asymptomatic outcome.

The data initially were analyzed by the Student's *t* test. A multivariate statistical analysis of the relationship between thoracic circumference to abdominal circumference and neonatal outcome was implemented. For this analysis an ordinal variable was constructed to reflect neonatal outcome (1 = neonatal death with pulmonary hypoplasia; 2 = clinical diagnosis of pulmonary hypoplasia; 3 = benign neonate; 4 = asymptomatic neonate).

Pearson correlation coefficients were computed to determine the relationship of thoracic circumference to abdominal circumference to gestational age at rupture; duration of rupture; age at birth; absolute thoracic circumference; and absolute abdominal circumference. A multiple regression model was used to measure the partial correlation between thoracic circumference to abdominal circumference and neonatal outcome, controlling for duration, age at onset of premature rupture of membranes, and age at birth. The purpose of this analysis was to test the hypothesis that the ratio of thoracic circumference to abdominal circumference affords information about neonatal outcome over and above that afforded by duration of premature rupture of membranes, age at onset of premature rupture of membranes, and age at birth.

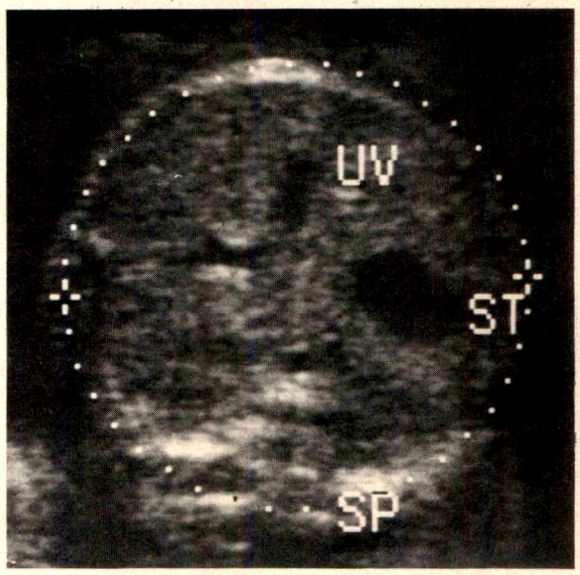

Fig. 2. Linear array ultrasound photograph showing a transverse section of the abdominal circumference with the fetal spine (*SP*), stomach (*ST*), and umbilical vein (*UV*).

Data of the premature rupture of membranes and oligohydramnios cases were then combined. A regression model was constructed for the ratio of thoracic circumference to abdominal circumference, age at birth, and indication (premature rupture of mem-

branes versus oligohydramnios). A partial correlation coefficient was then constructed for the combined indications.

Results

The ratio of thoracic circumference to abdominal circumference was associated with neonatal outcome. The lower thoracic circumference to abdominal circumference ratios were seen in the fetuses who later developed pulmonary hypoplasia (Figs. 3 and 4). All fetuses with thoracic circumference to abdominal circumference ratios >0.89 had either a benign or asymptomatic neonatal course. Of the 26 neonates alive at birth, 62% (n = 16) died. Table I lists the autopsy findings in each case. Group 1 accounted for 69% (n = 11), group 2 for 25% (n = 4), and group 3 for 6% (n = 1).

Table II compares the thoracic circumference to abdominal circumference ratio in premature rupture of membranes for the following parameters: death versus survival; group 1 versus groups 2, 3, and 4; and combined groups 1 and 2 versus groups 3 and 4. The difference in the thoracic circumference to abdominal circumference ratio was significant.

Table III compares the combined groups 1 and 2

Table II. Thoracic circumference to abdominal circumference ratio in premature rupture of membranes: Comparison of thoracic circumference to abdominal circumference ratio in 16 cases of premature rupture of membranes for death, autopsy-proved pulmonary hypoplasia, and clinical pulmonary hypoplasia

Table IV. Pearson correlation coefficients between neonatal outcome, thoracic circumference to abdominal circumference ratio, gestational age at onset of rupture, duration of rupture of membranes, absolute thoracic circumference, and absolute abdominal circumference in 16 cases of premature rupture of membranes

	*Outcome**	*TC to AC*
Thoracic circumference to abdominal circumference ratio	0.75 ($p < 0.001$)	1.0
Gestational age at premature rupture of membranes	0.71 ($p < 0.002$)	0.58 ($p < 0.02$)
Duration of premature rupture of membranes	−0.55 ($p < 0.03$)	−0.56 ($p < 0.02$)
Thoracic circumference (absolute)	0.69 ($p < 0.003$)	0.66 ($p < 0.003$)
Abdominal circumference (absolute)	0.18 (NS)	−0.06 (NS)

NS = Not significant.
*Values of outcome variables: 1 = neonatal death with pulmonary hypoplasia; 2 = clinical diagnosis of pulmonary hypoplasia; 3 = benign neonates; 4 = asymptomatic neonates.

versus groups 3 and 4 for the following parameters: duration of premature rupture of membranes, gestational age at premature rupture of membranes, and date of birth. The difference in duration and gestational age at onset of premature rupture of membranes was significant.

Table IV lists the correlation coefficients between the thoracic circumference to abdominal circumference ratio, outcome, gestational age at premature rupture of membranes, duration of premature rupture of membranes, absolute thoracic circumference, and absolute abdominal circumference. The thoracic circumference to abdominal circumference ratio correlated strongly with outcome ($r = 0.75$, $p < 0.001$).

The multivariate regression model of outcome in premature rupture of membranes, on the basis of age at onset, duration, and date of birth was significant ($R^2 = 51\%$, $p < 0.03$). The addition of the thoracic circumference to abdominal circumference ratio to the model increased the proportion of explained variability ($R^2 = 73\%$, $p < 0.01$). The partial correlation between the thoracic circumference to abdominal circumference ratio and outcome was 44%, indicating that 44% of variability in the regression model is accounted for by the inclusion of the thoracic circumference to abdominal circumference ratio.

The multivariate regression model of outcome, on the basis of age at birth and indication (premature rupture of membranes or oligohydramnios), was developed ($R^2 = 31\%$, $p < 0.02$). The addition of the thoracic circumference to abdominal circumference ratio to the model increased the proportion of explained variability ($R^2 = 68\%$, $p < 0.001$). The partial correlation between the thoracic circumference to abdominal circumference ratio and outcome was 54%, indicating that 54% of variability in the model is accounted for by the inclusion of the thoracic circumference to abdominal circumference ratio.

Correlation coefficients for oligohydramnios were not calculated. In these neonates, 89% were in group I ($n = 8$). The presence of congenital anomalies was noteworthy, including pulmonary hypoplasia, in all cases of oligohydraminos with a low thoracic circumference to abdominal circumference ratio.

Comment

Earlier reports have documented the significance of gestational age at onset of premature rupture of membranes and duration of premature rupture of membranes in the development of pulmonary hypoplasia.[5, 6] Similar findings were shown in this study. There was a correlation between neonatal outcome and duration of premature rupture of membranes ($r = 0.55$, $p < 0.03$). Also, the gestational age at onset of premature rupture of membranes correlated with neonatal outcome ($r = 0.58$, $p < 0.01$). Nimrod et al.[7] reported on the association of pulmonary hypoplasia and a low thoracic circumference. This study is in agreement with those findings by Nimrod et al. Thoracic circumference correlated strongly with outcome ($r = 0.69$, $p < 0.003$), but the thoracic circumference to abdominal circumference ratio correlated more strongly with outcome ($r = 0.75$, $p < 0.001$). No additional information was afforded by gestational age at birth.

The oligohydraminos group was not analyzed for significance of thoracic circumference to abdominal circumference because of the small sample size and the absence of information on onset and duration of oligohydramnios.

Decreased amniotic fluid is associated with pulmonary hypoplasia. Our study suggests that the thoracic circumference to abdominal circumference ratio affords valuable information in addition to duration of premature rupture of membranes, gestational age at onset of premature rupture of membranes, date of birth, absolute thoracic circumference, and absolute abdominal circumference.

We thank Joseph N. Bottalico, D.O., and Graham G. Ashmead, M.D., for their assistance in this project.

Effects of alterations of zinc-to-phosphorus ratios and meconium content on Group B *Streptococcus* growth in human amniotic fluid in vitro

Iffath Abbasi Hoskins, Commander, MC, USNR, Val G. Hemming, Colonel, MC, USAF, Timothy R. B. Johnson, M.D., and Craig A. Winkel, Colonel, MC, USA
Bethesda and Baltimore, Maryland

Several authors have described the bacterial growth-altering properties of amniotic fluid. We examined Group B *Streptococcus* growth in aseptically obtained amniotic fluid in vitro after altering its zinc, phosphorus, and meconium contents. Zinc and phosphorus levels were calculated in amniotic fluid and in meconium. Separate solutions of zinc and phosphorus were added to yield concentrations of 0.7, 7.0, 70, and 700 μmol. The solutions were incubated with Group B *Streptococcus* III 893 and *Escherichia coli* C5 strains, and 24-hour growth curves were plotted. Meconium, 0.5 mg/ml, was added to each amniotic fluid + zinc and amniotic fluid + phosphorus solution, and growth curves were plotted. The rate of proliferation of Group B *Streptococcus* varied directly with the zinc concentration (700 = 70 > 7 > 0.7 μmol) and inversely with the phosphorus content (700 < 70 < 7 = 0.7 μmol). Meconium enhanced the proliferative effect of zinc and hindered the inhibitory effect of phosphorus. Thus one possible mechanism whereby meconium enhances bacterial growth in amniotic fluid may be by alteration of zinc-to-phosphorus ratios. (AM J OBSTET GYNECOL 1987;157:770-3.)

Key words: Group B *Streptococcus* growth, amniotic fluid, zinc-to-phosphorus ratios, meconium content

The effect of amniotic fluid on bacterial growth in vitro has been studied extensively. However, the literature reports discrepant results regarding the effect of differing zinc and phosphate concentrations on the growth-inhibiting properties of the fluid. Schlievert et al.[1] described a low molecular weight peptide zinc complex, which acted as a bacterial growth inhibitor and was inactivated by phosphate. However, Blanco et al.[2] demonstrated the inhibition of Group B *Streptococcus* growth in amniotic fluid that contained increasing concentrations of phosphate. In a prior study,[3] we showed strain-specific differences in the in vitro growth patterns of Group B *Streptococcus* type III. A major purpose of the present study was to assess the effects of alterations in zinc-to-phosphorus ratios on strain-specific growth rates of Group B *Streptococcus* type III.

Previous workers have also described the growth-supporting properties of amniotic fluid in the presence of meconium. Florman and Teubner[4] have demonstrated the enhancement of growth of *Escherichia coli, Listeria monocytogenes*, and *Staphylococcus aureus* after the addition of meconium to amniotic fluid. They showed a striking increase in the number of organisims per milliliter in these fluids. Meis et al.[5] reported an association between the early passage of heavy meconium and amnionitis. A second purpose of this work was to study the in vitro growth patterns of Group B *Streptococcus* type III in amniotic fluid that contains meconium.

Material and methods

Sterile amniotic fluid specimens were obtained by amniocenteses performed during the second or third trimesters for chromosome or lung maturity studies, respectively. All patients were free of infection and were not taking any medications. Bloody, meconium-stained, or infected fluid was excluded. Each specimen was filtered through a 0.45 μm filter to remove cellular debris and then cultured to ensure sterility. All second-trimester amniotic fluid specimens were grouped into a single pool as were all third-trimester specimens. Zinc levels were measured after wet digestion with nitric-sulfuric acid, followed by measurement by atomic absorption at 214 nm in an air acetylene flame with a

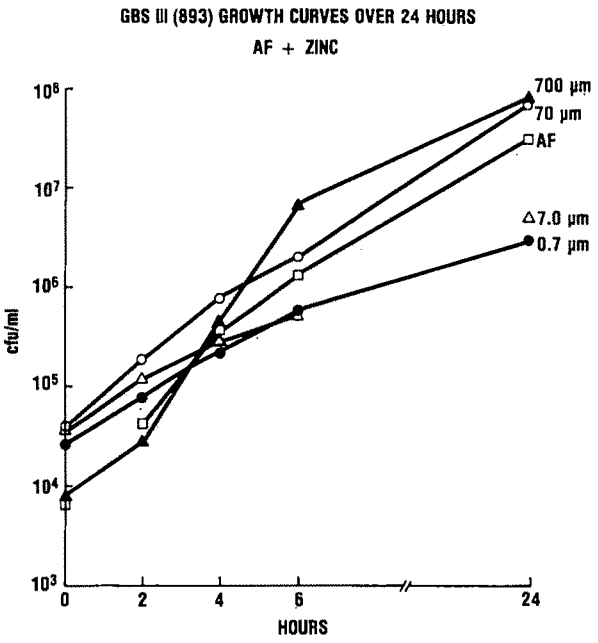

Fig. 1. The 24-hour growth curves of Group B *Streptococcus* III (893) in amniotic fluid and after the addition of zinc in varying concentrations.

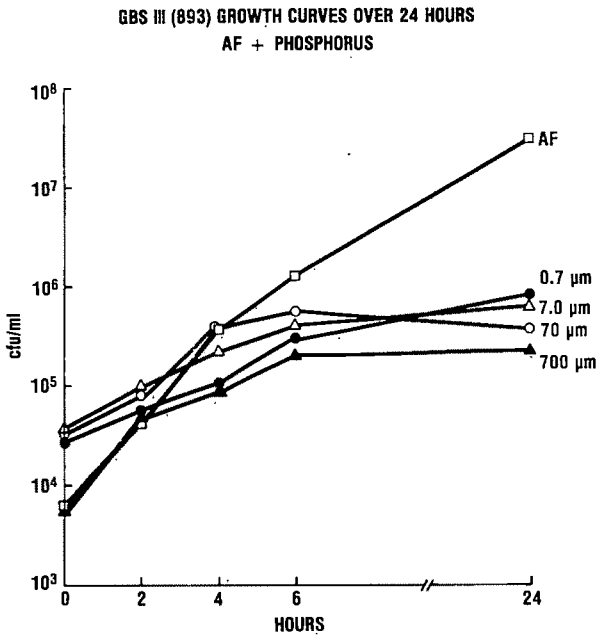

Fig. 2. Group B *Streptococcus* III (893) growth curves over 24 hours in amniotic fluid and after the addition of phosphorus in varying concentrations.

Perkin-Elmer atomic absorption instrument, model 603. Extensive precautions were required to avoid contamination of the samples by atmospheric dust, a common source of traces of zinc. All glassware was extensively washed with acid before use. Phosphorus was measured by the method of Lopez and Lowry and modified to measure phosphorus in the lowest ranges. Zinc-to-phosphorus ratios were calculated. Sterile solutions that contained zinc chloride were added to amniotic fluid aliquots in amounts that yielded the following concentrations of zinc: 0.7, 7.0, 70, and 700 μmol. These values were calculated to make molar solutions on the basis of the molecular weight of zinc. Sodium phosphate was added in amounts to yield concentrations of phosphorus 0.7, 7.0, 70, and 700 μmol. Aseptically obtained meconium was analyzed for its zinc and phosphorus contents, and a standard amount (0.5 mg/ml) was added to the amniotic fluid solutions that contained the above mentioned concentrations of zinc or phosphorus. Paired 2 ml aliquots of amniotic fluid were inoculated at zero time with approximately 1×10^4 colony-forming units per milliliter of a known virulent strain of Group B *Streptococcus* type III (893) or with *E. coli* (C5). Inocula were prepared by growing the bacteria to the log phase in Todd Hewitt broth, then adjusting the concentration with normal saline solution to approximately 1×10^3 colony-forming units per milliliter. Twenty microliters of the saline Group B *Streptococcus* or *E. coli* suspension were inoculated into the solutions previously prepared. The specimens were mixed well, aliquots removed for quantitative cultures, and incubation begun at 37° C. Two milliliter aliquots of Todd-Hewitt broth and of normal saline solution were used as positive and negative controls, respectively. Duplicate 10 μl aliquots were removed at 2, 4, 6, and 24 hours from each specimen. Quantitative cultures were performed by successive tenfold dilutions of each sample, followed by inoculation of a measured volume of each dilution onto Columbia sheep blood agar plates. After overnight incubation at 37° C, colony counts were performed.

Results

The zinc and phosphorus levels in the amniotic fluid were 192 and 0.90 μg/ml, respectively. The zinc-to-phosphorus ratios were >200, which is in the noninhibitory range, as described by Schlievert.[7] The growth curves of Group B *Streptococcus* type III (893) in the various amniotic fluid plus zinc solutions are shown in Fig. 1. The bacteria proliferated rapidly in these solutions at rates that equaled or exceeded their growth in amniotic fluid alone. The enhancement of bacterial growth varied with the concentration of zinc in the amniotic fluid: 700 and 70 μmol solutions caused a greater proliferation than the 7.0 μmol solution. The 0.7 μmol zinc solution caused the least profound bacterial growth. The 24-hour growth curves of Group B *Streptococcus* type III (893) in amniotic fluid plus phosphorus are shown in Fig. 2. The presence of phosphorus in the amniotic fluid samples resulted in inhibition of growth. This inhibition varied inversely with the concentrations of phosphorus (the higher concen-

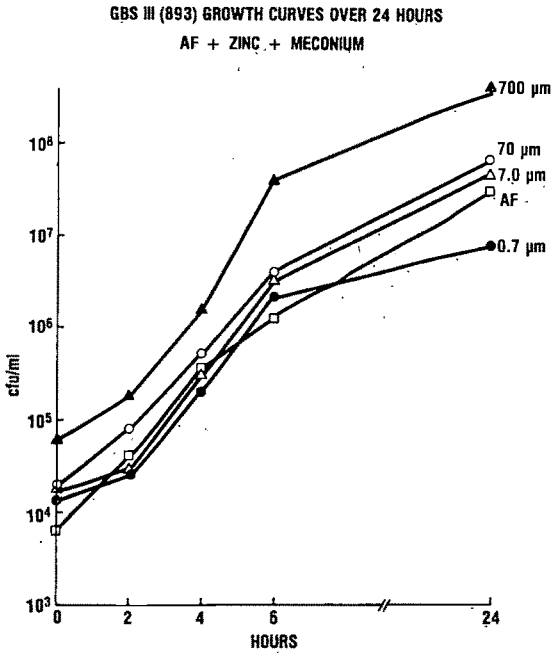

Fig. 3. Proliferation of Group B *Streptococcus* III (893) growth in amniotic fluid that contained zinc in the presence of meconium.

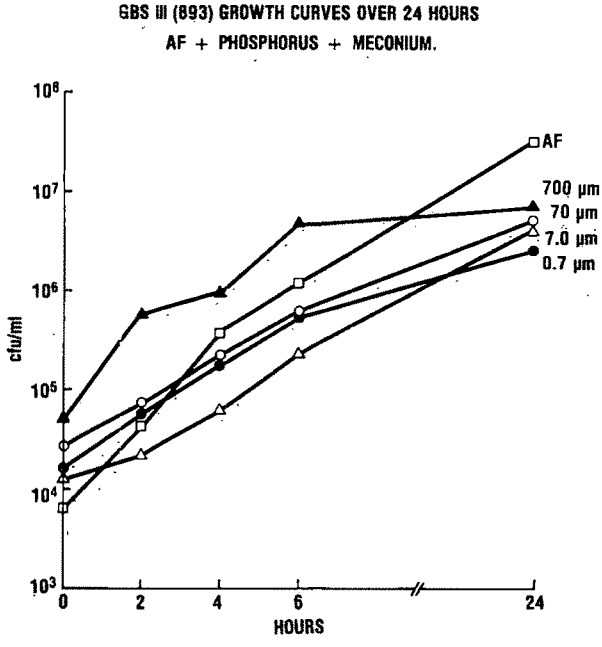

Fig. 4. Group III (893) over 24 hours after the addition of meconium to amniotic fluid that contained phosphorus.

trations were least inhibitory). The zinc and phosphorus contents in meconium were 70 and 128 µg/ml, respectively. The results of the addition of the meconium to the amniotic fluid plus zinc solutions are shown in Fig. 3. The addition of meconium resulted in the modulation of the growth-enhancing effect of the zinc, which thus demonstrated a 1- to 2-log increase in the number of organisms per milliliter after its addition to the amniotic fluid plus zinc solutions. The results of the addition of meconium to the amniotic fluid plus phosphorus solutions are shown in Fig. 4. Meconium blocked the growth-inhibiting effect of phosphorus on Group B *Streptococcus* growth, which showed a 1- to 2-log increase in the organisms, even though the overall growth was less proliferative than in amniotic fluid alone. Although the *E. coli* grew well in the fluid, their growth was inhibited by the addition of the zinc solutions and was enhanced by the addition of phosphorus to the fluid. These results are similar to those reported by Schlievert et al.,[7] who also described an inhibitory effect of zinc on the growth of *E. coli* with strain 06.

Comment

Group B *Streptococci* are important agents that influence perinatal morbidity and mortality. Although the literature describes various factors in amniotic fluid that impede bacterial growth, little is known about the influence of these factors on the prevention of Group B *Streptococcus* growth. Some human amniotic fluid specimens have impeded the in vitro proliferation of certain bacterial strains, whereas others have supported their vigorous growth. In a previous report,[3] we demonstrated the strain-specific variation in Group B *Streptococcus* growth curves in human amniotic fluid in vitro. Group B *Streptococcus* type III strains 893 and 891 proliferated more vigorously than strain 878.

Whether the zinc peptide inhibits Group B *Streptococcus* proliferation in amniotic fluid is not known with certainty. Schlievert et al.[7] isolated a zinc-dependent peptide from human amniotic fluid, which inhibited the proliferation of strains of *E. coli* 06, *S. aureus*, and *S. faecalis*. Further, they demonstrated that ratios of phosphorus to zinc in amniotic fluid may predict the in vivo activity of the peptide against the specific organism tested. A ratio of <100 was bactericidal; a ratio between 100 and 200 was bacteriostatic; and a ratio of >200 was described as noninhibitory. Others sought evidence to support the predictive value of phosphorus-to-zinc ratios with discrepant results. The findings reported in the present study are similar to those of Blanco et al.[2] These authors[2] have also described an inhibition of bacterial growth in the presence of phosphorus in amniotic fluid. Although the theory of Schlievert et al.[7] of the inhibitory effect of a zinc peptide on the growth of some organisms in amniotic fluid may be valid with certain bacteria such as *E. coli* and *S. aureus*, it apparently does not apply to Group B *Streptococcus*. Also, the growth of these organisms in the amniotic fluid plus phosphorus solutions differed from that of *E coli*. With *E. coli* the colony counts after

24 hours in the fluid plus phosphorus solutions exceeded their growth in amniotic fluid alone. The Group B *Streptococcus* colony counts at 24 hours in the amniotic fluid plus phosphorus solutions, however, were consistently 1- to 2-log units below the counts seen in amniotic fluid alone.

The reason for the differences may lie in the growth requirements of the Group B *Streptococcus*. As previously mentioned, Blanco et al.[2] have described the effects of differing phosphate concentrations on various species of streptococci.[2] The absence of phosphate decreases the growth of streptococci, but so does increasing the concentrations of phosphate. These requirements may have a role in the findings described in this study. Compared with the results of the growth curves of *E. coli*, the organisms proliferated with the addition of increasing concentrations of zinc to amniotic fluid, and their growth was inhibited by the addition of increasing concentrations of phosphate to the fluid. We can speculate that the pathogenicity of the Group B *Streptococcus* may vary not only with the specific strain but also with the differences in the levels of and therefore the ratios of zinc and phosphorus in amniotic fluid.

Several investigators[8-11] have demonstrated that amniotic fluid by itself is a poor culture medium for bacteria. However, Florman and Teubner[4] have shown that when relatively small amounts of meconium are added to the fluid, it becomes a good culture medium for bacterial growth. Our findings are similar and demonstrate the growth patterns of Group B *Streptococcus* in amniotic fluid after the addition of meconium. This growth is seen as an enhanced proliferation of the bacteria in the amniotic fluid solutions that contain zinc and a blocking of the inhibition of this growth in the amniotic fluid plus phosphorus solutions.

Meconium is a poorly defined and inconstant substance that contains various mucopolysaccharides and inorganic elements. It is unclear as to which of these elements converts amniotic fluid into a good culture medium for bacteria. One possible mechanism whereby this occurs may be by an alteration of the zinc-to-phosphorus ratios in the fluid, thus resulting in bacterial proliferation. These observations suggest that the fetus who is at risk for developing Group B *Streptococcus* infection from the mother and who remains in an environment that contains meconium may be at increased risk from this potentially lethal disease.

Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow

Kathryn L. Reed, M.D., Caroline F. Anderson, R.D.M.S., and Lewis Shenker, M.D.
Tucson, Arizona

Umbilical artery Doppler blood flow velocity studies were used to identify 14 fetuses with absent flow during diastole to determine the significance of absent umbilical artery diastolic flow. Outcomes of these fetuses were recorded, and the associated intracardiac Doppler changes were identified in 12 of them. Maximal and mean intracardiac flow velocities were measured, and volume flows through the right (tricuspid valve, pulmonary valve) and left (mitral valve, aortic valve) sides of the heart were compared. Ratios of intracardiac peak flow velocity in late diastole to peak flow velocity in early diastole were calculated. Eleven fetuses had intrauterine growth retardation, and four had multiple congenital anomalies. Fetuses with no diastolic flow in the umbilical artery had increased volume flow across the tricuspid and pulmonary valves compared with normal fetuses of similar weights. The ratio of right-sided to left-sided volume flow in the heart (2.15:1) was increased compared with values in normal fetuses (1.33:1, $p < 0.01$). The ratio of late diastolic to early diastolic peak flow velocities across the mitral valve was decreased ($p < 0.01$). Absent umbilical artery diastolic flow is associated with increased tricuspid and pulmonary valve volume flow and changes in mitral flow velocity patterns, which suggests that there are alterations in left ventricular function. (AM J OBSTET GYNECOL 1987;157:774-9.)

Key words: Fetal heart, Doppler

Doppler investigations of the umbilical artery have been reported to identify fetuses at increased risk for poor fetal outcome.[1-4] Normally, flow through the umbilical artery occurs in all phases of the cardiac cycle partly because of the low resistance of the placental circulation (Fig. 1).[1-4] Increased ratios of umbilical artery systolic to diastolic flow detected by Doppler investigation have been associated with increased perinatal morbidity and mortality and intrauterine growth retardation.[1-4] These studies attribute poor fetal outcome to placental vascular changes; however, examinations of the contribution of the fetal heart to the abnormal waveform and poor fetal outcome have not been performed. Placental vasculature in fetuses with intrauterine growth retardation has been reported to have increased resistance.[2-3] This increase in afterload for the fetal heart may result in changes that are detectable in utero.

Studies of intracardiac physiology in the human fetus witht Doppler are now possible.[5-10] Studies in normal fetal hearts indicate that volume flow is increased through the fetal right heart compared with the left heart.[6, 8, 9] Fetal intracardiac diastolic Doppler flow velocity waveforms reveal a high peak during late diastole (after atrial contraction) compared with the peak during early diastole.[7, 8]

The purpose of this study was to examine fetuses with no umbilical artery Doppler blood flow velocity during diastole, an extreme example of umbilical artery Doppler abnormality. We also studied the intracardiac Doppler flow velocities in these fetuses to document the changes in cardiovascular disease associated with absent umbilical artery diastolic flow.

Material and methods

Fetuses were examined with ultrasound for indications of a hypertensive disorder of pregnancy, suspected growth retardation, or suspected fetal anomaly. Permission was obtained from each mother to perform Doppler studies. Approval for this project had been obtained from the Human Subjects Committee.

Standard ultrasound measurements were obtained, including biparietal diameter, femur length, abdominal diameters, and estimated amniotic fluid volume. Placental location was identified, and general fetal anatomy was assessed. The fetal heart was examined in detail, including four-chamber, short-axis/great vessel, long-axis/great vessel, and arch (aortic and pulmonary artery) views. Cardiac valve diameters were measured with two-dimensional images.

Umbilical artery pulsed Doppler waveforms were recorded from at least four regions with 10 beats each.

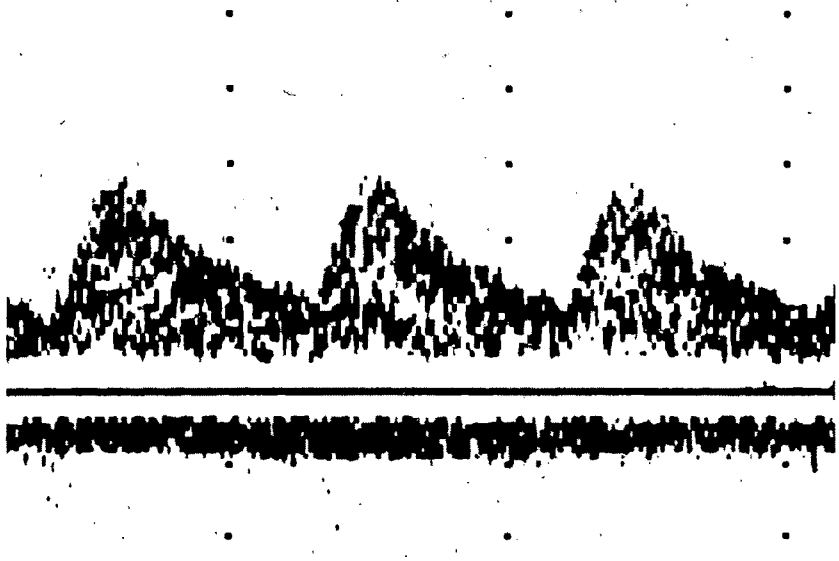

Fig. 1. Doppler flow velocity tracing of the umbilical artery and vein in a normal fetus.

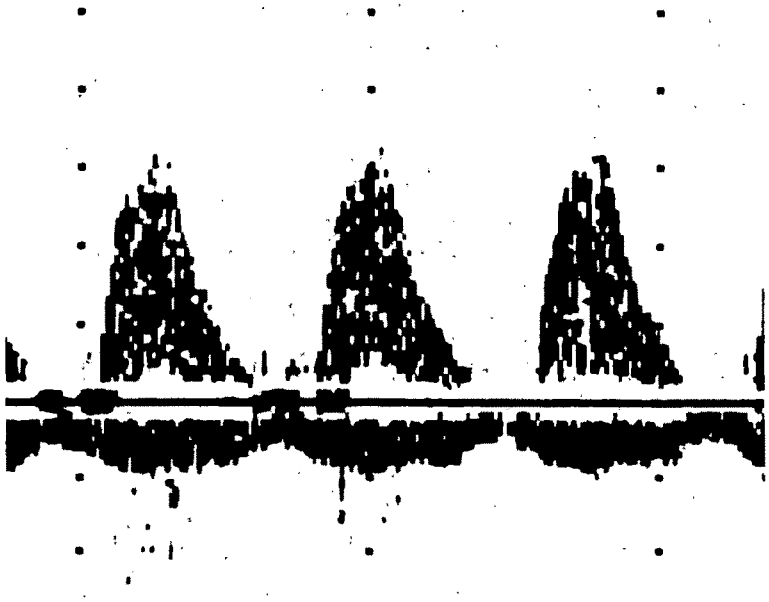

Fig. 2. Doppler flow velocity tracing of the umbilical artery and vein in a fetus with absent diastolic umbilical artery blood flow. Velocity decreases to zero after each peak. Fluctuations in venous flow velocity are not caused by fetal breathing or movement.

Fetuses were included in the study if no umbilical artery flow was present during diastole (Fig. 2).

Pulsed Doppler investigations of the intracardiac chambers and great vessels were performed as previously described.[6] With two-dimensional guidance, the pulsed Doppler gate was placed immediately distal to the valve leaflets of the cardiac region being sampled. The direction of blood flow was estimated to be perpendicular to the valve anulus. Velocity measurements were accepted if the angle of insonation was <30 degrees from the estimated direction of blood flow. Maximal and mean velocity measurements were obtained from page print outputs from a strip chart recorder. Maximal velocity was measured from the zero line to the highest point of the velocity peak. Temporal mean velocity was calculated by planimetering the area beneath the gray scale spectral velocity display and dividing by the time over which the velocity was traced.

Table I. Tricuspid and mitral valve values (mean ± SEM)

	Normal[6,7] *(n = 47)*	*No diastolic flow (n = 12)*	*p*

Diameter (mm)	6.7 ± 0.2	6.6 ± 0.2	NS
Volume flow (ml/kg/min)	250 ± 9	222 ± 9	NS

Volume flow was calculated by multiplying mean velocity by the area (πr^2), through which blood was flowing. Neonatal weights were used for calculating volume flow.

Two-dimensional and Doppler measurements obtained from patients in the study were compared with those of normal fetuses of similar weights, which have been reported elsewhere.[6, 7, 9] Values reported are mean ± SEM, except where otherwise noted.

The instrument used was a 3.5 MHz scanner with pulsed Doppler capability. According to the manufacturer's specifications, fetuses were exposed to <46 mW/cm^2 ultrasound power density. Pregnancies were managed without relying on Doppler information. The outcomes of the fetuses were recorded, including method and reason for delivery, weight, Apgar scores, admission to the intensive care unit, and presence of congenital anomalies. The statistical method used was Student's *t* test for unpaired values, with significance at 0.05.

Results

Fourteen fetuses were included in this series, with intracardiac studies in 12 fetuses. Maternal age was 24.6 ± 5.2 (mean ± SD) years, gravidity was 2.4 ± 1.7, and parity was 0.9 ± 1.1. Hypertensive disorders complicated 71% of the pregnancies, and fetal anomalies were suspected in 29%. Amniotic fluid volume was decreased or absent in 57%.

Vaginal deliveries occurred in 43% of the patients; in only one case was this a vertex vaginal delivery of a live infant and consisted of midforceps for fetal distress. Cesarean sections were performed in eight of 14 (57%), in each case for fetal distress, defined by the presence of late decelerations detected with electronic fetal monitoring. Four (29%) fetuses died in utero, three with known anomalies (trisomy 13, suspected trisomy 13, and trisomy 21); one mother of an otherwise normal fetus refused cesarean section with late decelerations with electronic fetal monitoring. Pericardial or pleural effusions were present in four fetuses. In total, four (29%) of the fetuses had multiple congenital anomalies, including the trisomic fetuses, and one had hypoplastic lungs and polycystic kidneys. Two neonates died, one of multiple congenital anomalies and one of unknown causes. All live fetuses were admitted to the neonatal intensive care unit. Eleven (78%) were growth-retarded by institutional standards. Two of three fetuses without growth retardation were anomalous (one with cystic hygromas and trisomy 21 and one with polycystic kidneys). The total perinatal mortality was 42%.

The mean fetal biparietal diameter was 6.9 ± 1.2 cm

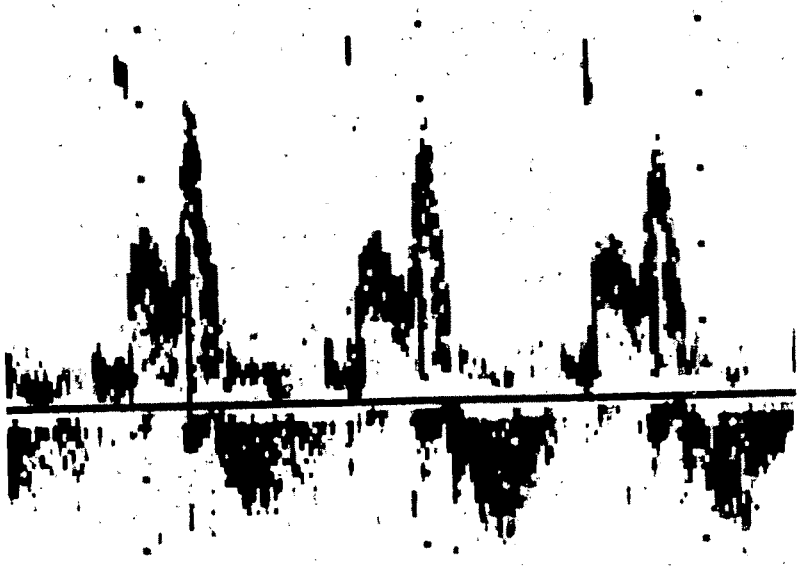

Fig. 3. Doppler flow velocity tracing across the mitral valve in a normal fetus. Two peaks are normally present during diastolic flow, one in early diastole (E) and one in later diastole (A). In the normal human fetus, the A is usually higher than the E, resulting in an A-to-E ratio of >1.

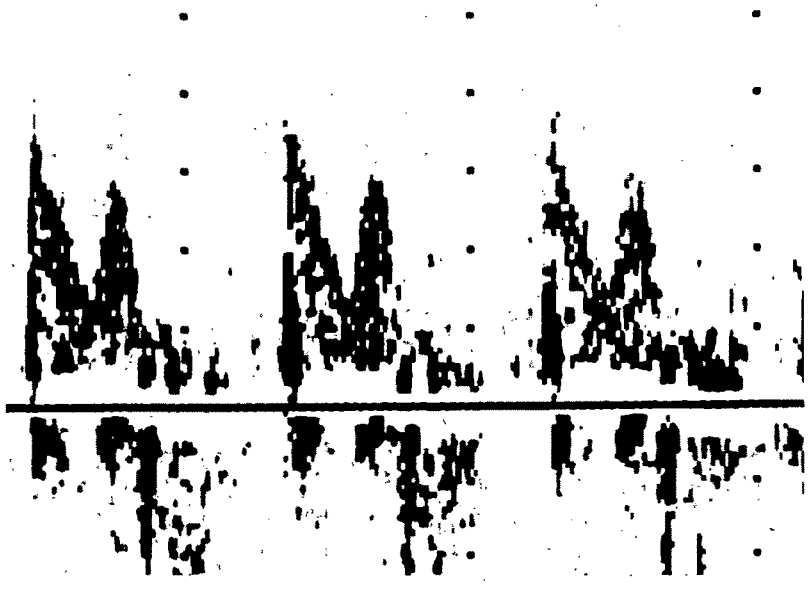

Fig. 4. Doppler flow velocity tracing across the mitral valve in a fetus with absent umbilical artery diastolic flow. A-to-E ratio is <1.

(mean ± SD), mean fetal femur length was 5.2 ± 1.0 cm, and mean estimated gestational age at diagnosis was 32 ± 5 weeks. Deliveries or fetal death occurred an average of 6 days after diagnosis (range, 0 to 27 days). Mean neonatal weight was 1227 ± 255 gm, with a 1-minute Apgar score of 5 ± 3 and a 5-minute Apgar score of 7 ± 3.

The two-dimensional ultrasound and Doppler results are shown in Tables I and II. Tricuspid and pulmonary volume flows were increased compared with normal values. The ratio of peak flow velocity during late diastole to peak flow velocity during early diastole was decreased (Table I, Figs. 3 and 4). Tricuspid valve measurements (maximal velocity, $p < 0.05$; mean

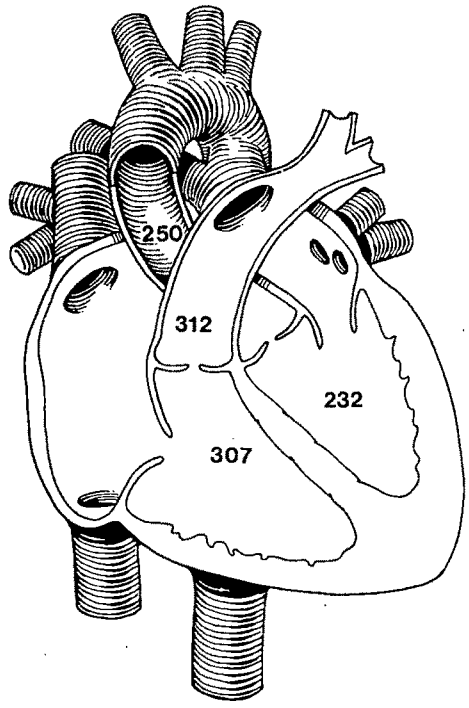

Fig. 5. Volume flow in the normal fetal heart. Numbers represent milliliters per kilogram per minute. *307* = Tricuspid valve, *312* = pulmonary valve, *232* = mitral valve, and *250* = aortic valve.

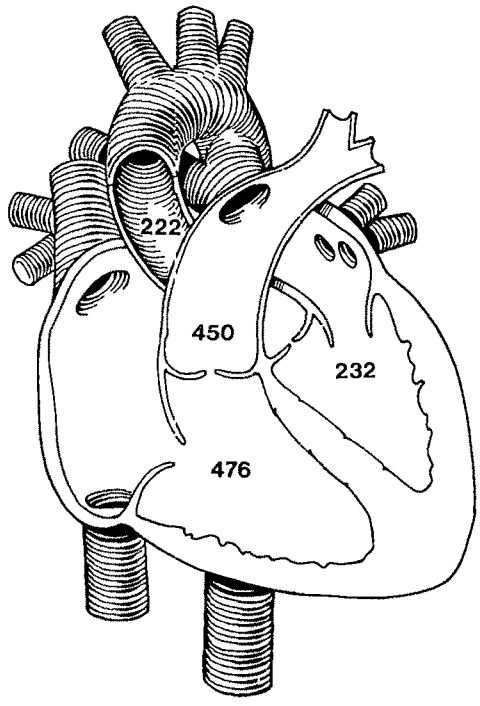

Fig. 6. Volume flow in the heart of a fetus with absent diastolic flow in the umbilical artery. Numbers represent milliliters per kilogram per minute. *476* = Tricuspid valve, *450* = pulmonary valve, *232* = mitral valve, and *222* = aortic valve.

velocity, $p < 0.01$; diameter, $p < 0.05$; and volume flow, $p < 0.05$) were greater than those of the mitral valve in the abnormal group. Pulmonary valve measurements (mean velocity, $p < 0.001$; diameter, $p < 0.01$; and volume flow, $p < 0.001$) were greater than those of the aortic valve in the abnormal group. The ratio of tricuspid valve to mitral valve volume flow was increased ($2.32 \pm 0.03:1$) compared with normal ($1.37 \pm 0.05:1$, $p < 0.01$). The ratio of pulmonary valve to aortic valve flow was also increased ($2.15 \pm 0.03:1$) compared with normal ($1.33 \pm 0.02:1$, $p < 0.001$, Figs. 5 and 6). In individual fetuses no significant differences were found when tricuspid valve volume flows were compared with pulmonary valve volume flows (right-sided flows) and mitral valve volume flows were compared with aortic valve volume flows (left-sided flows).

Comment

Changes in the pattern of blood flow velocity in the umbilical artery are thought to reflect placental function and fetal well-being.[1-4] In the normal fetus, the ratio of systolic to diastolic flow decreases with advancing gestational age. If this trend is reversed and the ratio is increased, an abnormality of the fetoplacental vasculature may be present. An extreme example of this is the umbilical artery Doppler flow velocity waveform without flow during diastole, which is therefore highly abnormal.

In this report, umbilical artery Doppler flow velocity studies were used to identify fetuses with absent blood flow velocity during diastole. Perinatal morbidity (100%) and mortality (42%) were markedly abnormal in this group. Intracardiac Doppler studies were performed in these fetuses to examine the physiologic changes in the fetal heart that accompany these abnormal umbilical flow velocity patterns. Volume flows were increased on the right side of the fetal heart (tricuspid and pulmonary artery valves) compared with the left side of the heart (mitral and aortic valves) and compared with normal fetuses of similar weights.

Previous studies of intracardiac volume flow in normal fetuses have shown that the fetal right heart volume flows are greater than left heart volume flows by a ratio of $1.3:1$.[6, 8] In this study we found an even greater increase in the right heart flow, with a tricuspid valve–to–mitral valve volume flow ratio of $2.32:1$ and a pulmonary valve–to–aortic valve volume flow ratio of $2.15:1$. Left heart volume flow was unchanged compared with normal. In addition, a decrease in the ratio of late diastolic peak flow velocity to early diastolic peak flow velocity in the mitral valve suggested that there may also be a change in the diastolic function in the fetal left ventricle.

Our findings regarding fetal outcome are consistent with previous investigators who showed almost identical data (cesarean section for fetal distress, 75%; perinatal mortality, 40%[11]) in fetuses with no flow in the umbilical artery during diastole. Our report is the first investigation to our knowledge that attempts to examine the pathologic mechanism that may be responsible for these outcomes.

One possible explanation for the intracardiac changes we report is that developing hypoxia results in dilation of the cerebral vasculature, as evidenced indirectly by fetal cerebral artery studies. These studies indicate that a decrease in the ratio of systolic to diastolic measurements in the cerebral arteries is associated with the development of fetal growth retardation.[12] In addition, in hypoxic neonates, the pulmonary vasculature constricts while the ductus enlarges. To increase volume blood flow to the brain from the left ventricle, in the face of a dilated ductus supplied by the right ventricle, volume flow must increase across both ventricles. This interpretation is consistent with the findings of our study, with increased volume flow through the right side of the heart and increased combined ventricular output.

The alteration in flow across the mitral valve with a shift to more flow in early diastole is interesting. Previous investigators have shown that the normal fetal ventricle is noncompliant[13]; Doppler investigations have shown that the fetal diastolic function changes with advancing gestational age in a pattern consistent with gradually increasing compliance.[7] The changes in mitral flow velocity waveforms seen in this study of abnormal fetuses may be based on a relative increase in left ventricular volume, which results in dilation and increased compliance. Increases in right and left ventricular diameters have been reported in the presence of fetal growth failure.[14]

We conclude from this study that the presence of umbilical artery blood flow velocity waveforms with no flow during diastole is associated with an increase in perinatal morbidity and mortality. Alterations in intracardiac Doppler flow velocity waveforms are detectable in these fetuses. These changes may explain the pathophysiology in the cardiovascular system that accompanies fetal growth failure and fetal distress.

Enhancement of maternal and neonatal natural killer cell activity with interleukin-2

David A. Baker, M.D., Peter O. Milch, Ph.D., William Salvatore, B.S., and Benjamin Luft, M.D.
Stony Brook, New York

Natural killer cell activity, which is vital to the immune surveillance against viruses and tumor cells, is significantly lower in the newborn infant than in the mother. Incubation of maternal and cord blood lymphocytes with interleukin-2 significantly increases natural killer activity in both. The increase is substantially greater in the cord blood lymphocytes. (AM J OBSTET GYNECOL 1987;157:780-1.)

Key words: Natural killer cell activity, cord blood, interleukin-2

Natural killer cells are reported to be important in immune surveillance destruction of viruses and tumor cells.[1] Studies have shown that newborn infants have low natural killer activity. This study was undertaken to establish whether interleukin-2, a known immunomodulator,[2] can enhance natural killer cell activity in maternal and cord blood lymphocytes.

Material and methods

Fifteen pairs of samples of maternal and cord blood were obtained at the time of delivery. All deliveries were singleton, at term, and without complications. The protocol was previously approved by the Investigational Review Board. Lymphocytes were separated by Ficoll-Hypaque density centrifugation, washed with and resuspended in RPMI-1640, which contained 10% fetal calf serum. Natural killer cell activity was determined with a 4-hour chromium 51 release assay with K 562 cells as targets. Overnight incubation of lymphocytes, with and without interleukin-2, was at 37° C in the presence of 5% carbon dioxide. All assays were performed at four effector to target ratios (100, 50, 25, and 12.5:1). An aliquot of the lymphocytes obtained in four of the 15 sets of blood samples was labeled with the Becton-Dickinson monoclonal antibodies Leu 7 and Leu 11 that identify natural killer cells.

A total of 10,000 cells was counted in each determination of Leu 7^+ and Leu 11^+ cells with a fluorescence-activated cell sorter. Statistical analyses were done with Student's paired *t* test.

Results and comment

As shown in Table I, cord blood natural killer activity is significantly lower than that of the maternal blood

Table I. Effect of interleukin-2 on natural killer activity and percent of Leu 7^+ and Leu 11^+ cells in maternal and cord blood samples (effector to target ratio, 50:1)

	Day 0	*Day 1*	*Day 1 + 20 U/ml interleukin-2*		*Day 1 + 80 U/ml interleukin-2*
Natural killer activity (mean ± SEM)					
Maternal (n = 15)	25.4 ± 4.7	18.0 ± 2.3	$p < 0.0003$	39.3 ± 5.7	43.1 ± 4.7
	$p < 0.04$				
Cord (n = 15)	14.0 ± 2.2	15.7 ± 3.5	$p < 0.0$	30.2 ± 5.4	48.6 ± 6.9
Increase (%) (mean ± SEM)					
Maternal (n = 15)				211.4 ± 11.2	256.8 ± 17.9
				$p < 0.05$	$p < 0.04$
Cord (n = 15)				306.5 ± 41.6	374.7 ± 46.7
Leu 7^+					
Maternal (n = 4)	11.6 ± 3.0	9.3 ± 2.5		11.8 ± 3.0	13.0 ± 2.0
Cord (n = 4)	4.4 ± 1.8	4.2 ± 1.9		5.2 ± 2.1	4.9 ± 1.8
Leu 11^+					
Maternal (n = 4)	17.6 ± 3.9	17.6 ± 3.5		19.4 ± 3.8	18.5 ± 3.0
Cord (n = 4)	17.4 ± 2.9	19.5 ± 2.8		20.7 ± 3.1	20.5 ± 30

on the day of delivery (day 0). Overnight incubation with 20 U/ml interleukin-2 shows a significant increase in natural killer activity in both sets, compared with the lymphocytes incubated alone (day 1). However, the increase in the cord blood natural killer activity is significantly greater than that of the maternal blood. Incubation with 80 U/ml interleukin-2 showed further increases in natural killer activity, but they were not significantly different when compared with incubation with 20 U/ml interleukin-2. Table I presents the natural killer activity data at a 50:1 effector to target ratio. At the other effector to target ratios of 100:1, 25:1, and 12.5:1, the findings were identical. Leu 11^+ cells were identical in the two groups, but there was a decrease in Leu 7^+ cells in cord blood. Interleukin-2 treatment resulted in no changes. The data suggest that natural killer activity in the newborn infant requires maturation and that this process can be enhanced by interleukin-2. Additional investigations with animal models with specific viral infections (herpesvirus and cytomegalovirus) could define these relationships of natural killer cells, their function in viral infection, and their potentiation with lymphokines. Interleukin-2 might have efficacy in the newborn infant's antiviral therapy; however, this can be proved only with careful detailed studies in animals and in vitro.

Maternal serum α-fetoprotein screening: Effects of weight adjustment

To the Editors:

In the August 1986 issue of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY, Dr. Macri (Macri JN. Critical issues in prenatal maternal serum α-fetoprotein screening for genetic anomalies. AM J OBSTET GYNECOL 1986;155:240) suggested that adjustment of the maternal serum α-fetoprotein for maternal weight would have a negative effect on the screening process. He based his argument largely on the data of Wald et al.[1] published in 1981, which showed that in pregnancies in which the fetus is affected with open spina bifida, the maternal weight was found to be approximately 1.6 kg less than that in unaffected pregnancies. Dr. Macri further stated that had weight adjustment been incorporated into the interpretations of maternal serum α-fetoprotein results in his screening population, "a significant reduction of NTD detection efficiency would have occurred." Both Dr. Wald and Dr. Macri are concerned with the relatively small woman whose maternal serum α-fetoprotein level may be only slightly elevated and in whom adjustment for maternal weight will move the value into the normal range.

Neither author addressed the issue of weight adjustment in the large woman in whom a neural tube defect might be missed because of an unadjusted value that falls within the normal range; nor did they address the issue of weight adjustment at the lower end of the scale, where weight adjustment may affect the decision to offer amniocentesis for detection of chromosomal abnormalities.

Other investigators have demonstrated that adjustment for maternal weight can increase the specificity of the test with no loss in sensitivity[2] and that weight correction is especially important if α-fetoprotein levels are to be used to predict the risk of neural tube defects or trisomy 21.[3]

Our experience in Maryland in screening 7116 women supports the rationale of weight adjustment. We multiply the multiple of the median value by the ratio of the patient's weight to 135 pounds. The following case studies illustrate the utility of this adjustment.

In Case 1, a woman weighing 214 pounds had a maternal serum α-fetoprotein result of 60.1 ng/ml or 1.6 multiples of the median for 17 weeks' gestation. No further workup was indicated with this interpretation. However, after correction for the maternal weight, the maternal serum α-fetoprotein value became 2.5 multiples of the median and a repeat sample was requested.

The second maternal serum α-fetoprotein value, determined at 18 weeks' gestation, was 75.1 ng/ml or 1.9 multiples of the median, corrected for weight to 3.0 multiples of the median.

Level II ultrasound showed fetal meningomyelocele, hydrocephalus, and scoliosis.

The amniotic fluid α-fetoprotein was 4.0 multiples of the median and the acetylcholinesterase test results were strongly positive. Chromosomes were normal.

In Case 2, a 31-year-old woman weighing 115 pounds had a maternal serum α-fetoprotein result of 11 ng/ml or 0.4 multiple of the median for 16 weeks. The lower cutoff of the laboratory at this time was 0.3 multiple of the median (regardless of age). With correction for the maternal weight of 115 pounds the maternal serum α-fetoprotein multiple of the median decreased to 0.3 and amniocentesis to rule out Down syndrome was offered. A diagnosis of trisomy 21 was made by chromosomal analysis.

The Maryland State Health Department α-Fetoprotein Laboratory, which incorporated weight adjustment into its maternal serum α-fetoprotein interpretations, has not missed any neural tube defects because of a reduction of the maternal serum α-fetoprotein values in the group of women whose borderline elevated values were adjusted into the normal range because of maternal weight. We have, on the contrary, avoided many unnecessary amniocenteses in these patients. More importantly, we have diagnosed one case of open spina bifida and one case of trisomy 21 that might otherwise have been missed.

We would be interested in specific figures from Dr. Macri's screening program to illustrate his point concerning a negative effect on detection in the group of "small women." We would also be interested in data from other screening programs related to their experience with adjustment of the maternal serum α-fetoprotein value for maternal weight.

Reply

To the Editors:

We are pleased to respond to the comments of Ms. Kazazian, Dr. Niebyl, and Dr. Joseph on maternal weight data presented in our August 1986 article.

Some concerns raised by these authors were addressed by us in a subsequent article in October 1986 entitled, "Maternal serum α-fetoprotein screening, maternal weight, and detection efficiency."[1] A review of this more recent communication from our laboratory would have removed their concerns that we based our argument largely on data from others, that we are concerned with relatively small women, and that we did not address the issue of weight adjustment in large women. Data presented in our October 1986 article demonstrates that our concerns about maternal weight adjustment stem from our analysis of a sizable pregnancy population and the effect of weight adjustment by three published methods. Applied to our data, all three methods result in a larger proportion and a different group of women being alerted to the need for further evaluation, and in two of the three methods detection efficiency* is negatively influenced.

Kazazian et al. refer to Palomaki et al.[2] and state that: "Other investigators have *demonstrated* (italics added) that adjustment for maternal weight can increase the specificity of the test with no loss in sensitivity. . . ." Analysis of data from Palomaki et al. reveals that conclusions drawn in their article are based on assumptions and estimates and not on achieved detection efficiency. In fact, it is unclear to us why Palomaki et al. chose to base their conclusions on assumptions rather than use actual patient data and pregnancy outcome. In the 2 years since publication of the article by Palomaki et al., empirical data and pregnancy outcome information to support their theory have not appeared from them or others. We are unclear therefore as to how Kazazian et al. can claim the "demonstration" of the effectiveness of maternal weight adjustment.

Kazazian et al. indicate that their screening experience in Maryland supports the rationale of weight adjustment. In fact, the method of weight adjustment suggested by the Johns Hopkins group (multiplying the actual multiple of the median value by the ratio of maternal weight to 135 pounds) is quite different from published methods suggested by other investigators (the absolute α-fetoprotein value is divided by an expected α-fetoprotein value to determine an adjusted multiple of the median). The Johns Hopkins group, however, do not present data concerning the scientific basis for or the specific effect of their new approach. We have therefore applied their approach to the same pregnancy population evaluated in our October 1986 article in which three published weight adjustment methods were assessed. The Johns Hopkins group method resulted in the reclassification of (1) 65 patients as having normal levels and (2) 147 patients as having elevated levels. This method demonstrates an even more unfavorable net effect of weight adjustment as it relates to reclassification of maternal serum α-fetoprotein levels into the elevated category than those three methods evaluated in our October 1986 article. Inasmuch as the Johns Hopkins group method has not been published and since no explanation was provided by Kazazian et al., readers will be confused as to whether a decision not to reclassify patients into the elevated category (as recommended by Wald et al.[3]) is followed by these authors. Irrespective of the false positive issue, the Johns Hopkins group method also results in a loss in detection efficiency (one of four cases of open spina bifida reclassified as having a normal level).

To support the beneficial aspects of their weight adjustment approach, Kazazian et al. presented two case reports. Careful analysis of these case reports reveals some specific concerns. First, it is clear that the median maternal serum α-fetoprotein values at 16, 17, and 18 weeks are 27.5, 37.6, and 39.5 ng/ml, respectively. This represents an unusual increase in median levels between 16 and 17 weeks (36.7%) and only a small increase between 17 and 18 weeks (5.05%). These differences are contrary to what is known of weekly increases in maternal serum α-fetoprotein. Indeed material from the Maryland maternal serum α-fetoprotein screening program indicates that in their data base, normative data for weeks 20 to 25 were estimated on the basis of the assumption that α-fetoprotein increases by 15% per week. The above Maryland data for 16 to 18 weeks' gestation do not support this assumption. The effect of such unusual maternal serum α-fetoprotein normative data on the percentage of elevated samples, as well as on detection efficiency, causes concern. This concern is heightened when we consider the following statements from one α-fetoprotein quality assessment scheme[4] (in which the Maryland maternal serum α-fetoprotein program participates): "In most cases the problems with interpretation arise from inaccurate reference data (medians). Examination of assay results in conjunction with supplied medians, reveals that in some cases the problems lie with inappropriate medians, either much too low or too high. In addition, medians in some cases are inconsistent, i.e. do not increase by the expected 12% to 18% per week, with the result that multiple of the median calculations are highly erratic depending on the gestational age of the specimen."

Second, Kazazian et al. use a cutoff of 0.3 multiple of the median (regardless of age) when screening for Down syndrome. Although screening for Down syndrome is in an investigative stage, a 0.3 multiple of the median cutoff does not seem adequate. It should be noted that preliminary data indicate that the median α-fetoprotein level for Down syndrome cases is 0.7 mul-

*Data presented in our article pertain to maternal serum α-fetoprotein screening for structural malformations. Effect of weight adjustment on Down syndrome screening is under investigation.

tiple of the median; so the use of a 0.3 multiple of the median cutoff could potentially lead to poor detection efficiency. Additionally, since the incidence of Down syndrome increases substantially with age, failure to incorporate age in determining risk will result in misinterpretation of low values of α-fetoprotein.*

With regard to Kazazian et al.'s Case 2, the patient's weight-adjusted multiple of the median is 0.34. Inasmuch as 0.34 multiple of the median is higher than the authors' 0.3 multiple of the median cutoff, we are unclear as to why their laboratory alerted clinicians to the need for further evaluation in this case.

Kazazian et al. concluded by stating that the Maryland State Health Department has not missed an open neural tube defect because of maternal weight adjustment and, on the contrary, has avoided many unnecessary amniocenteses. They did not reveal, however, (1) the mathematical basis for their weight adjustment system, (2) the number of cases on which it is based, (3) how many pregnancies either (a) avoided further testing or (b) were directed to go on for further testing because of weight adjustment, or (4) their overall program detection efficiency for open neural tube defects. All information concerning weight adjustments published by others to date presents a concept that is based on estimates and assumptions but fails to present empirical data to demonstrate the beneficial effects of this statistical adjustment.

The data presented in our October 1986 maternal weight article illustrate our point concerning a negative effect on detection efficiency. Finally, we share with Kazazian et al. an interest in empirical data from other screening programs related to their experience with weight adjustment of maternal serum α-fetoprotein values.

*We disagree with the use of the multiple of the median statistical parameter for reporting and decision making. Patient-specific risk reporting is clinically preferable.[5,6]

Drug prescribing for thromboembolic disease during pregnancy

To the Editors:

Drs. Rayburn and Lavin have done obstetricians a great service in summarizing the current treatment of common disorders complicating pregnancy (Rayburn WF, Lavin JP Jr. Drug prescribing for chronic medical disorders during pregnancy: an overview. Am J Obstet Gynecol 1986;155:565-9). Their protocol for treating thromboembolic disease assumes physicians have a reliable heparin assay available. Unfortunately, most hospitals do not offer tests of heparin levels although they do provide reliable activated partial thromboplastin time determinations.

We have a simplified approach to the treatment of thromboembolic diseases such as deep venous thrombosis or pulmonary embolism. Our regimen, modified from the protocol of Hull et al.,[1] utilizes the activated partial thromboplastin time. The initial treatment in the hospital with intravenous heparin is the same; however, after at least 7 days of therapy patients are switched to heparin administered subcutaneously every 12 hours. The initial daily subcutaneous dose used is two thirds of the total intravenous dose required during 24 hours to maintain a therapeutic activated partial thromboplastin time. The daily subcutaneous dose is divided into two doses given every 12 hours. Thus, if a patient requires intravenous heparin at 1000 units/hr, the total daily intravenous dose is 24,000 units. The patient receives two thirds of this dose (16,000 units) divided into 8000 units subcutaneously every 12 hours. The activated partial thromboplastin time is measured 6 hours after the subcutaneous heparin dose, and the heparin dose is adjusted until a therapeutic activated partial thromboplastin time is achieved (one and a half to two times control). This regimen has proved satisfactory in our hospital in more than 50 cases of deep vein thrombosis. Physicians who do not have a heparin assay available at their hospitals may find our approach acceptable.

The treatment of pregnant patients with prosthetic heart valves who require anticoagulation is much more controversial. A recent consensus conference recommended that these patients be treated during pregnancy with subcutaneous heparin every 12 hours in a dose that prolongs the activated partial thromboplastin time to the therapeutic range (one and a half to two times control) 6 hours after the injection.[2] It is recognized that adequate clinic studies to support this recommendation are lacking.

There are not adequate data to be certain that subcutaneous heparin is the optimal regimen. Oakley and Doherty[3] reported a case of thrombosis of a Hammersmith-Alvarez prosthetic mitral valve in a patient treated with "full anticoagulant doses of heparin subcutaneously."

Despite the risk that heparin will fail to prevent some thromboembolic complications, the alternative, coumarin, is unacceptable. In their classic review, Hall et al.[4] showed that pregnancies exposed to coumarin derivatives had the following outcomes: abnormal live birth, 1/6; abortion or stillbirths; 1/6; and apparently normal births; 2/3.

Iturbe-Alessio et al.[5] recently reported an even higher incidence of coumarin embryopathy: 25% (two of eight) in pregnancies exposed from conception to the seventh to eleventh week and 29.6% (eight of 27) in pregnancies treated with acenocoumarol during all three trimesters.

Other anticoagulant regimens that are ineffective or complicated by hemorrhage include minidose heparin and continuous subcutaneous heparin infusions. Minidose heparin (5000 units subcutaneously every 12 hours) has no place in the prevention of thromboembolism in pregnant patients with prosthetic heart valves requiring anticoagulation. Four of 10 patients treated by Chen et al.[6] had thromboembolism during pregnancy while being treated with minidose heparin. The use of continuous subcutaneous heparin infusion for anticoagulation during pregnancy was associated with major bleeding complications requiring transfusion in four of six patients treated.[7] These regimens should be abandoned.

There is a need to collect information on the outcome of pregnancy in patients with prosthetic heart valves requiring anticoagulation, who are treated with adjusted-dose subcutaneous heparin.

Lymphocyte-reactive antibodies and recurrent early pregnancy failure

To the Editors:

It was with interest that we read the latest report by Unander and Lindholm on the use of leukocyte-rich erythrocyte concentrate transfusions in women with recurrent early pregnancy failure (Unander AM, Lindholm A. Transfusions of leukocyte-rich erythrocyte concentrates: a successful treatment in selected cases of habitual abortion. Am J Obstet Gynecol 1986;154: 516-20). Recognizing the risks associated with transfusion for viral transfer (human immunovirus, hepatitis, and cytomegalovirus)[1] as well as detrimental sensitization (blood groups, platelet and classical histocompatibility or HLA antigens), these authors retrospectively identified some individuals with recurrent unexplained abortions who would not benefit from leukocyte transfusions. Although limited variables were reported, it was concluded that women without "blocking" antibodies are the women who benefit from third-party transfusions. Because Unander and Lindholm's study was not randomized, they failed to acknowledge the 20% to 60% of subjects that may have been able to carry a pregnancy to term without transfusion treatment. Antipaternal cytotoxic antibodies were not studied as a criterion of those who would not benefit from transfusions, as only 20% to 50% of multiparous women have such antibodies. In contrast, the presence of antipaternal cytotoxic antibodies was a major exclusion criterion used by Mowbray et al.[2] in their "controlled trial" of women with recurrent spontaneous abortion immunized with paternal cells.

In trying to clarify those subjects who may not require immunotherapy, data concerning the expected frequency of blocking antibodies in women with primary and secondary abortion would have been elucidating. After the report by Mowbray et al., we set out to define an expected frequency for the presence of cytotoxic antibodies in women who are recurrent spontaneous aborters. We chose to study nulliparous women with (1) three or more elective abortions and (2) three or more spontaneous abortions, without a viable pregnancy progressing beyond 12 weeks in both groups.

Venous blood was obtained from these women at 4 to 12 weeks after their last elective abortion. Serum lymphocytotoxic antibody was assessed at room temperature by complement-dependent lysis against a panel of 30 individuals' peripheral blood lymphocytes in a 1½-hour two-stage technique at 22° C.[3] Only one of 23 (4%) "recurrent elective aborters" exhibited lymphocytotoxic antibodies. For comparison, the incidence of antibody observed in the sample of primary recurrent spontaneous aborters was 8/63 (13%).

We recognize that our control population may not

be ideal because of the lack of monogamous relationships in recurrent elective aborters and the use of a panel of lymphocytes encompassing the major HLA-A and HLA-B specificities rather than "paternal" lymphocytes. However, we believe that the use of multigravid nulliparous women as a reference control is important for studies concerning women with unexplained recurrent spontaneous abortions. Our results suggest that primary aborters with antipaternal cytotoxic antibodies may in fact represent an infrequent but normal response to a first-trimester pregnancy. Albeit not tested, these women may not benefit from lymphocyte transfusions, similar to the situation in women with "blocking" antibodies.

It is regrettable that further randomized controlled studies of recurrent spontaneous aborters with and without leukocyte transfusions appear to be passé. Without a prospective control group, it will be difficult to identify those women who do not need leukocyte transfusion and its associated risks.

RESPIRATORY CONTROL AND LUNG DEVELOPMENT IN THE FETUS AND NEWBORN

(0-916859-12-6) 1986

Eds: B.M. Johnston & P.D. Gluckman.

20 Contributors

Authors are the major contributors to this important area of perinatal medicine. Volume reviews the structural and biochemical basis of prenatal and perinatal pulmonary development, and of the neural and chemoreceptor development of respiratory control. Includes historical overview of the rediscovery of fetal breathing and it's consequences.

Essential reading for perinatologists, obstetricians and neonatologists.

". . . A feast of information . . . updating . . . knowledge of pulmonary pathophysiology during fetal life . . . " Brit.J.Ob.Gyn.

DOPPLER ULTRASOUND MEASUREMENT OF MATERNAL-FETAL HEMODYNAMICS

(0-916859-29-0) 1987

Eds: D. Maulik & D. McNellis.

20 Contribututions from internationally acknowledged leaders in the field, including Recommendations.

Workshop convened by the NICHD to assess the current and potential use of Doppler measurement of maternal-fetal hemodynamics. Volume considers all aspects from the latest fundamental developments to the required characteristics for use in fetal and pregnant studies.

Medical Staff Fellowships In Genetics, Endocrinology, And Developmental Biology At NIH

The National Institute of Child Health and Human Development of the National Institutes of Health is offering a limited number of three-year Medical Staff Fellowship positions to candidates of the highest caliber. Fellowships begin July 1, 1989 and 1990. Positions are available for physicians who have completed at least two years of training in Internal Medicine, Pediatrics, or Obstetrics and Gynecology. Other medical specialty credentials will be considered on a case by case basis. Candidates must be United States citizens or permanent residents; graduates of foreign medical schools must be certified by the ECFMG. (Non-citizens wishing only laboratory experience may apply for the Fogarty Visiting Fellowship and do not need ECFMG certification.)

The training program consists either of one clinical year and two years of laboratory-based research (satisfying the requirements for the Subspecialty Boards in Human Genetics, Adult or Pediatric Endocrinology, or Gynecologic Endocrinology), or three years of laboratory research exclusively. The endocrinology fellowships are integrated with the NIH Interinstitute Endocrinology Fellowship Program, and the human genetics fellowships are integrated with the NIH Interinstitute Medical Genetics Program. The gynecologic-endocrinology fellowship is integrated with programs at the Walter Reed Hospital and the National Naval Medical Center.

For those selecting clinically oriented fellowships, research experience will be obtained in the Laboratory or Branch of the Fellow's choice from among the Institute's three clinical research Branches and nine basic science Laboratories. For those candidates selecting laboratory research exclusively, these same choices are available.

The major emphasis of the NICHD Intramural Research Program is on basic and clinically applied research in the broad area of developmental biology. Areas presently being examined include developmental endocrinology, reproductive biology, cellular differentiation, human genetics and inborn metabolic errors, molecular endocrinology, developmental and molecular immunity, developmental neurobiology, molecular genetics (bacteria, virus, yeast, drosophila, and animal cell), pharmacogenetics, growth factors, neurochemistry and neuroimmunology, theoretical and physical biology, cell biology (especially receptors and organelles), and comparative ethology.

For physicians interested in pursuing a career in academic medicine and research, these Fellowships offer an opportunity to train with scientists and physicians of international stature. Excellent facilities are available on the 306-acre NIH campus in Bethesda, Maryland, including a 480-bed research and teaching hospital, more than 1,000 laboratories, and the National Library of Medicine. Medical Staff Fellows receive an initial salary of $30,000 with increments of $2,000 per year. Moving and traveling allowances, and Federal health care benefits are available.

Interested candidates should send their curriculum vitae to (or request further information from):

Arthur S. Levine, M.D., Scientific Director,
National Institute of Child Health and Human Development,
National Institutes of Health, 9000 Rockville Pike,
Building 31, Room 2A50, Bethesda, Maryland 20892, (301) 496-2133

NIH is an Equal Opportunity Employer.

Deadline for applications is November 15, 1987.

GYNECOLOGIST/OBSTETRICIAN IN SUN CITY WEST, ARIZONA

Outstanding private practice opportunity exists for a Board Certified/Eligible Obstetrician/Gynecologist. Del E. Webb Memorial Hospital is the centerpiece of a 81 acre health care campus scheduled to open in January 1988. Office space is currently available for leasing.

Our campus is centrally located between Sun City West, a large affluent retirement community and the rapidly growing needs of nearby family-oriented communities.

The Sun City West area of Metropolitan Phoenix, offers exciting professional and recreational opportunities. As part of the Sun Health Corporate family, Del E. Webb Memorial is able to offer the reputation, experience and technologies enjoyed by its seasoned, affiliated divisions. The casual, southwestern lifestyle is especially appealing with several nearby lakes, resorts, golf courses and attractive housing.

If interested in additional information regarding this opportunity, contact:

Lee Peterson, Executive Vice-President, Del E. Webb Memorial Hospital.

OB-GYN TEACHING FACULTY AT TRUMAN Medical Center/East, one of two teaching hospitals for the University of Missouri-Kansas City School of Medicine. Joint faculty appointments in Departments of Family Medicine and OB-GYN. Primary responsibilities teaching OB and office GYN to Family Practice residents, performing GYN surgery, some lesser involvement with medical students, and consultation in high-risk pregnancy problems as they present. Competitive salary, excellent fringes, opportunities for additional practice, if desired. Contact Family Medicine Department, University of Missouri-Kansas City School of Medicine, Truman Medical Center-East, 7900 Lee's Summit Road, Kansas City, MO 64139. (816) 373-6228. Attention: Thomas A. Nicholas, M.D., Chairman.

GYNECOLOGIC ONCOLOGISTS

The Department of Reproductive Medicine, University of California, San Diego is seeking applicants for full time Assistant, Associate or full Professor faculty positions in the section of Gynecologic Oncology. One of the positions is that of Division Director. Activities will include patient care, research, and teaching at the medical student and postgraduate level. Qualified applicants should be Board Certified or Eligible (Active Candidate Status in general Obstetrics and Gynecology and Gynecologic Oncology. Appointment at the Assistant, Associate or full Professor level, as well as tenure track, is dependent upon previous experience. Salary related to rank and step of appointment is within the established salary schedule at the University of California, San Diego School of Medicine. Please send curriculum vitae and three names and addresses for recommendation before October 31, 1987 to:

Robert Resnik, M.D.
Professor and Chairman
Department of Reproductive Medicine
U.C.S.D. Medical Center
225 Dickinson Street
San Diego, California 92103

The University of California is an Equal Opportunity/Affirmative Action Employer

PERINATOLOGISTS

Three full-time positions are available as perinatologists in Maternal-Fetal Medicine in the Department of OB/GYN, U.C. Davis Medical Center, Sacramento. Applicants should be Board eligible or certified in OB/GYN and must have successfully completed subspecialty training in Maternal-Fetal Medicine with subsequent Specialty Board eligibility and/or certification. Applicants must demonstrate experience and competence in teaching effectiveness and research related activities. Applicants must demonstrate experience in prenatal diagnosis, ultrasound and genetics.

Responsibilities include inpatient and outpatient case management, surgery and procedures specific to high risk obstetrics, participation in teaching activities with residents, interns and medical students, development and/or participation in research activities and involvement in University and Hospital committees.

Send curriculum vitae and five references to:

R. Jeffrey Chang, M.D.
Chairman, Department of Obstetrics and Gynecology
University of California, Davis, Medical Center
1621 Alhambra Boulevard, Suite 2500
Sacramento, California 95816

The final date for receipt of appplications is "Open until filled, but not later than April 1, 1988"

The University of California, Davis is an equal opportunity, affirmative action employer.

FACULTY POSITIONS
DEPARTMENT OF OBSTETRICS AND GYNECOLOGY
UNIVERSITY OF TEXAS SOUTHWESTERN MEDICAL SCHOOL
DALLAS, TEXAS

INSTRUCTORS: Applicants must have completed an accredited residency in Obstetrics and Gynecology. Applicants will participate in clinical care of women at Parkland Memorial Hospital and Maternal Health and Family Planning patients. Must be eligible for a Texas license.

ASSISTANT PROFESSORS: Applicants must have completed an accredited residency in Obstetrics and Gynecology and a two-year Fellowship in Maternal-Fetal Medicine or Reproductive Endocrinology. Applicants will participate in clinical care of women at Parkland Memorial Hospital and Maternal Health and Family Planning patients. Must be eligible for a Texas license.

Interested persons should send curriculum vitae to:

F. Gary Cunningham, M.D.
Professor and Chairman
Department of Ob-Gyn
University of Texas
Southwestern Medical School
5323 Harry Hines
Dallas, Texas 75235-9032

An equal opportunity employer

MATERNAL - FETAL MEDICINE

JEFFERSON MEDICAL COLLEGE OF THOMAS JEFFERSON UNIVERSITY

Two Board certified/eligible Periontologists needed for rapidly growing university service. Excellent opportunity for research, teaching and high risk clinical practice. Address inquiries to:

Ronald J. Wapner, M.D.
Director, Division of
Maternal-Fetal Medicine
or
Richard Depp, M.D.
Professor and Chairman

Department of Obstetrics and Gynecology
Jefferson Medical College
Thomas Jefferson University
1025 Walnut Street
Room 310
Philadelphia, PA 19107

Equal Opportunity Employer

ASSOCIATED PROFESSOR OF PEDOPATHOLOGY

The University of Lausanne opens a registration in order to be able to set up a position of

Associated Professor
of Pedopathology and of
pathology of the development

at the Institute of pathology.

The candidate must teach, prepare research programs particularly in the field of development and guarantee the diagnostic tasks.

The conditions or terms must be obtained from the Dean of the School of Medicine.

The candidatures must be sent to:

Professor M. DOLIVO,
Dean of the School of Medicine
9 rue du Bugnon,
1005, Lausanne
Switzerland

Before October 15, 1987.

CHAIRMAN
DEPARTMENT OF OBSTETRICS AND GYNECOLOGY

The University of Pittsburgh School of Medicine is conducting a search for the Chairman of the Department of Obstetrics and Gynecology and Chief of Service at the Magee Womens Hospital of Pittsburgh. Candidates should have achieved national recognition for research and should have a demonstrated commitment to patient care and education. Extensive experience in administration is desirable. Applications and nominations, including a curriculum vitae, should be sent by November 30, 1987 to:

Dr. Thomas J. Gill III Chairman
Search Committee for Chairman of OB/GYN
University of Pittsburgh
School of Medicine
716 Scaife Hall
Pittsburgh, PA 15261

The University of Pittsburgh is an
Equal Opportunity/Affirmative Action Employer

POSITION AVAILABLE
DIRECTOR OF
OBSTETRICS AND GYNECOLOGY

Board certified obstetrician-gynecologist to direct clinical services and educational programs at Metropolitan Nashville General Hospital in Nashville, Tennessee. The hospital is affiliated with the Vanderbilt University Medical Center and the Meharry Medical College.

Faculty rank, tenure and salary are commensurate with experience.

Send C.V. to:

Lonnie S. Burnett, M.D.
Professor and Chairman
Department of Obstetrics and Gynecology
Vanderbilt University Medical Center
Nashville, Tennessee 37232

OR

Henry W. Foster, M.D.
Professor and Chairman
Department of Obstetrics and Gynecology
Meharry Medical College
1005 D. B. Todd, Jr. Boulevard
Nashville, Tennessee 37208

LOS ANGELES
OB/GYN

Immediate opening is available for female/male Board Certified or eligible to join OB/GYN group. Excellent salary and fringe benefits including full malpractice covrage.

Please send curriculum vitae to:

MJV
16530 Ventura Blvd.
Suite 205
Encino, CA 91436

SOUTH CAROLINA

HERE'S WHAT MOSBY'S BOUND VOLUMES CAN ADD TO YOUR PRACTICE!

Handsomely bound in durable buckram, with rich gold stamping, bound volumes are important to every successful practice.

A Bound Volume:
- gives quick and easy access to important journal articles
- eliminates problems with missing issues or pages
- makes your regular subscription a "working" copy to mark up, tear from, or file
- offers an inexpensive and easy way to guarantee bound reference volumes—prices include shipping

You Must Order Now!
Bound volumes are made up from over-run copies of each journal issue. You never worry about sending out (or finding) your personal copies. But to over-run enough copies we need your order today!

Bound volumes are only available to current subscribers and may not be ordered in place of a regular journal subscription. Payment must accompany your order. Bound volumes are nonreturnable.

Credit Card Orders Call FREE:
1-800-325-4177, ext. 351
In Missouri, call collect: (314) 872-8370, ext. 351

OBSTETRICS AND GYNECOLOGY REVIEW

honoring Robert Scully, M.D.

*Any Six Days — December 1-9, 1987 — Chicago

Now, your only BOARD REVIEW just before Oral Exams is also an excellent update for surgeons and preview for Written Exar

OBJECTIVES

- Increase basic knowledge in obstetrics and gynecology
- Improve clinical skills in diagnosis and treatment
- Assist residents and fellows in organizing study
- Prepare board candidates to pass board examinations
- Provide practicing surgeons with a review and update

METHODS

- HOME STUDY MATERIALS with questions and ansv based on previous examinations
- SEMINAR with projection slides and syllabus
- LABORATORY with microscopic slides
- PRACTICE EXAMS with oral and written parts

* Dec. 1-6 (live); Dec. 7-9 (Video replay of Dec. 1-3). Any consecutive six days will complete program.

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

21-and 28-day regimens

ORTHO-NOVUM 777 Tablets

norethindrone/ethinyl estradiol TRADEMARK

ach white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg orethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl stradiol. Each green tablet in 28-day regimen contains inert ingredients.

MPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the roduct and therefore should not be used as the basis for prescribing the product. This summary was prepared by eleting from the complete prescribing information certain text, tables, and references. The physician should be oroughly familiar with the complete prescribing information before prescribing the product.

NDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

OSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive ssociation between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is rudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive roduct prescribed for any given patient should be that product which contains the least amount of estrogen that is ompatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral ontraceptives be started on preparations containing .05 mg or less of estrogen.

ONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. hrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic isorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or uspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may ause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who re pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard o the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral ontraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and hrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great ritain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism nd stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times nore likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary mbolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **EREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in onusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study onducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than hat of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study onducted in the United States found that past use of oral contraceptives was associated with increased risk of ubarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk nay be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial nfarction associated with the use of oral contraceptives has been reported confirming a previously suspected ssociation. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of nderlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, iabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether he patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk actor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive sers was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 00,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as ikely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold ncreased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. n determining the importance of these relative risks, however, the baseline rates for various age groups must be given erious consideration. The importance of other predisposing conditions mentioned above in determining relative and bsolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a esser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists ollowing discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British nvestigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher isk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an ndependent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. Cases of hepatocellular carcinoma, although rare, have been reported in women taking oral contraceptives. Retrospective studies conducted in the United States and Britain report an increased risk of hepatocellular carcinoma in oral contraceptive users, particularly with increased duration of use. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **DRUG/LABORATORY TEST INTERACTIONS:** The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

ORTHO

Beyond low dose...

EXCELLENT RESULTS

Low incidence of nuisance side effects†
Low breakthrough bleeding
Low impact on selected metabolic parameters

21- and 28-day regimens

ORTHO-NOVUM 7/7/7 Tablets

TRADEMARK

norethindrone/ethinyl estradiol

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

Please see brief summary of complete Prescribing Information on the preceding page.

...on oral contraception:

"The multiphasics contain a low dose of progestin without having an increased incidence of breakthrough bleeding."[3]

"The preferred progestin is the estrane norethindrone and not the gonane norgestrel...if changes in HDL and HDL_2 levels are to be avoided...."[4]

Low BTB with Tri-Norinyl

- Extra midcycle protection that's unique among multiphasics
- Low BTB rates—equivalent to a fixed low-dose OC[2]

Low Impact with Tri-Norinyl

- Minimal lipid and cholesterol impact[4]
- Low incidence of nuisance side effects[2]

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

THE LOWEST-DOSE MULTIPHASIC OC WITH NORETHINDRONE

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of prescribing information on next page.

TRI - NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. (See also Warnings, 4. *Liver Tumors.*) 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. Cases of hepatocellular carcinoma have been reported in long-term users of OCs.[105-107] An epidemiological study suggested a 4-fold increase in relative risk for hepatocellular carcinoma in OC users for 8 years or more, which increased to 7 in women with markers of hepatitis B. A second study suggested a risk of about 20 for use in excess of 8 years. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero.* These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests that the incidence of *Chlamydia trachomatis* infection, the leading cause of nongonococcal PI.D., is increased by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Budd-Chiari syndrome, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure, premature supraventricular contractions. **Information for the Patient** (See Patient Package Insert).

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

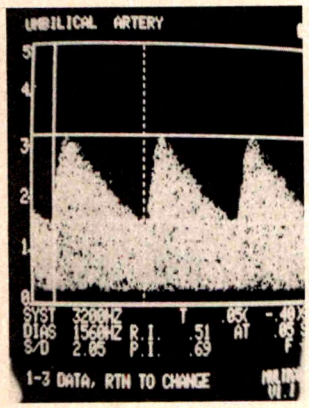
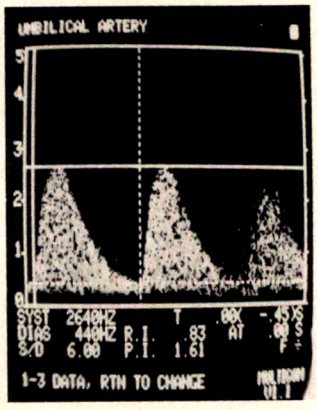
500A™ UMBILICAL-UTERINE ARTERY DOPPLER SPECTRUM ANALYZER

LETS YOU EVALUATE

UTEROPLACENTAL PERFUSION BY SPECTRUM ANALYSIS OF UMBILICAL AND MATERNAL UTERINE ARTERY DOPPLER WAVEFORMS



CLINICAL RESULTS[1-8] SHOW THAT YOU CAN:



- DETECT *IUGR* FROM 20 WEEKS IN SINGLETON PREGNANCIES AND 30 WEEKS IN TWIN PREGNANCIES
- USE UTERINE ARTERY WAVEFORMS IN THE MANAGEMENT OF MATERNAL PREECLAMPSIA
- USE UMBILICAL ARTERY VELOCITY WAVEFORMS IN THE MANAGEMENT OF DIABETIC PREGNANCIES

Umbilical and uterine artery waveforms are easily obtained from early pregnancy on. Low power continuous wave Doppler spectrum analysis is used in a simple test to measure the peripheral resistance in the placental circulation. This resistance is measured by taking the ratio of the systolic to diastolic (S/D) velocity. The S/D ratio is compared to established normal values to determine the presence of abnormal resistance.

The Model 500A™ automatically computes the systolic to diastolic ratio as well as resistance and pulsatility indices.

Normal Umbilical Waveform
S/D = 2.05

Abnormal Umbilical Waveform
S/D = 6.00

A life of substance? Or substance abuse?

You would like to know that each baby you deliver will have a life of substance. But unfortunately, because of the extent of drug abuse in our society, more and more babies are born drug addicts—sentenced to a life of substance abuse.

You, as a physician, are in a position to do something about it. During her initial workup, simply ask your patient about drug use. It's no more an invasion of privacy than asking about exposure to German measles. It's just as important to her baby's health. And it may prevent serious problems for you, mother, and baby.

Help free this generation—and the next—from drugs.

You'll never know unless you ask.

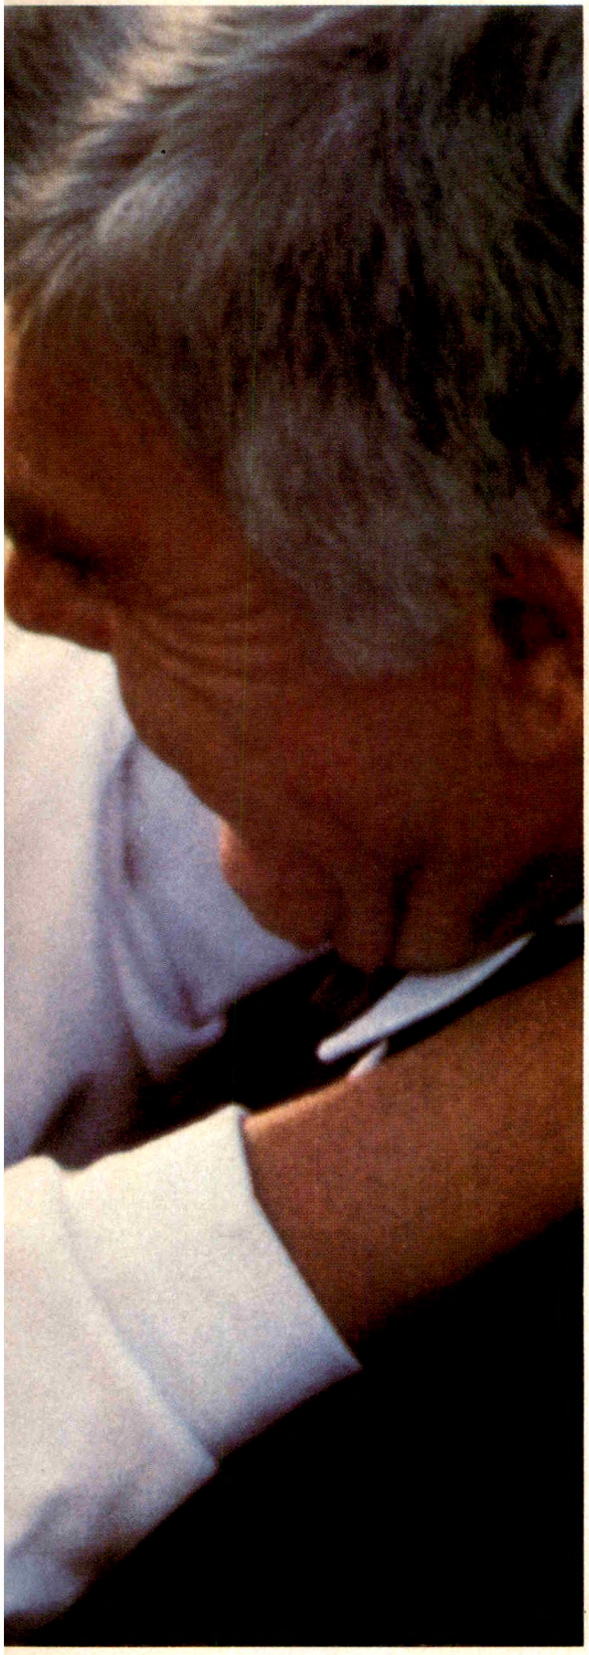
Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.



Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by The C. V. Mosby Company for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page is paid directly to CCC, 29 Congress St., Salem, MA 01970; phone (617)744-3350. The U.S. Government retains a nonexclusive, royalty-free license in and to any copyright on articles authored by government employees. 0002-9378/87 $00.00 + .10.

There's never been a better time for her.

nd PREMARIN®

Proven benefits beyond relief of vasomotor symptoms

No other estrogen proven effective for osteoporosis

Only conjugated estrogens tablets have established efficacy in both osteoporosis[1] and vasomotor symptoms* at 0.625 mg/day. No other estrogen, oral or transdermal, has established clinical evidence or minimum effective dose in both indications.

No estrogen proven safer

PREMARIN is the most extensively tested estrogen, with an unsurpassed record of long-term safety.
And clinical evidence shows a significantly reduced risk of endometrial hyperplasia when cycled with a progestin.[2]

PREMARIN®
(conjugated estrogens tablets)

Most trusted for more reasons

*PREMARIN is indicated for moderate-to-severe vasomotor symptoms.

Please see following page for brief summary of prescribing information.

For moderate-to-severe vasomotor symptoms and for osteoporosis

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equi-estrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: PREMARIN (conjugated estrogens tablets, USP): Moderate-to-severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. (See PRECAUTIONS.) The choice of progestin and dosage may be important; product labeling should be reviewed to minimize possible adverse effects.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not yet complete. If concomitant progestin therapy is used, potential risks may include adverse effects on carbohydrate and lipid metabolism.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. However, in a recent, large case-controlled study of postmenopausal women there was no increase in risk of breast cancer with use of conjugated estrogens.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration. Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off). Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

LEVLEN™

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

The lowest total hormonal dose in a monophasic OC formula

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. The physician should be aware of the complete prescribing information for this product. Please also see brief summary of prescribing information on the next page.

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

BRIEF SUMMARY

Each Levlen tablet contains 0.15 mg of levonorgestrel (d (-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.03 mg of ethinyl estradiol (19-nor-17 α-pregna-1,3,5 (10)-trien-20-yne-3,17-diol) (7 pink inert tablets are included in Levlen 28).

Indications and Usage—Levlen is indicated for the prevention of pregnancy in women who elect to use OCs as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only OCs have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. (The rates given for Pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutiv periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribe schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the la menstrual period if the progestogen-only OCs are used), and further use of OCs should be withheld until pregnancy has been ruled ou If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of th pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinician recommend 3 months, although no precise information is available on which to base this recommendation. The administration progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnanc

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, a increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase triglycerides and total phospholipids has been observed in patients receiving OCs. The clinical significance of these findings remain to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertensio may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in use and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposur and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated wit the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely t develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to norma after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule ou pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing t an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessar since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in progestogen-only O failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving OCs, since the drugs are mor effective in preventing intrauterine than ectopic pregnancies.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity an quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should b deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatmen and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 yea without another physical examination being performed.

2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patient becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in a attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should b prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundic during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patien receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients wit impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in norma tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8 Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

Information for the Patient—See patient package labeling.

Laboratory Tests—1. The pathologist should be advised of OC therapy when relevant specimens are submitted.

2. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs:

a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3 increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use o rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline

Carcinogenesis, Mutagenesis, Impairment of Fertility—See "Warnings" section #3, 4 and 5 for information on carcinogenesis mutagenesis and impairment of fertility.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings." Because of the potential for adverse reactions in nursing infants from OC tablets, a decisior should be made whether to discontinue the drug, taking into account the importance of the drug to the mother.

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (se "Warnings"): thrombophlebitis; pulmonary embolism; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertensior gallbladder disease; benign hepatomas; congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies ar needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/o vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Othe reactions, as a general rule, are seen much less frequently or only occasionally; gastrointestinal symptoms (such as abdominal cramp and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness enlargement and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possibl diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening) intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; ner vousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis porphyria; hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Levlen must be taken exactly as directed and at interval not exceeding 24 hours.

Any time the patient misses 1 or 2 light-orange tablets, she should also use another method of contraception until she has taken light-orange tablet daily for 7 consecutive days.

For full details on dosage and administration, see prescribing information in package insert.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Zuspan is responsible for articles from the Society for Gynecologic Investigation. Manuscripts should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033. Dr. Quilligan is responsible for articles from The Society of Perinatal Obstetricians. Manuscripts should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Edi-

tor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

Medical Staff Fellowships In Genetics, Endocrinology, And Developmental Biology At NIH

The National Institute of Child Health and Human Development of the National Institutes of Health is offering a limited number of three-year Medical Staff Fellowship positions to candidates of the highest caliber. Fellowships begin July 1, 1989 and 1990. Positions are available for physicians who have completed at least two years of training in Internal Medicine, Pediatrics, or Obstetrics and Gynecology. Other medical specialty credentials will be considered on a case by case basis. Candidates must be United States citizens or permanent residents; graduates of foreign medical schools must be certified by the ECFMG. (Non-citizens wishing only laboratory experience may apply for the Fogarty Visiting Fellowship and do not need ECFMG certification.)

The training program consists either of one clinical year and two years of laboratory-based research (satisfying the requirements for the Subspecialty Boards in Human Genetics, Adult or Pediatric Endocrinology, or Gynecologic Endocrinology), or three years of laboratory research exclusively. The endocrinology fellowships are integrated with the NIH Interinstitute Endocrinology Fellowship Program, and the human genetics fellowships are integrated with the NIH Interinstitute Medical Genetics Program. The gynecologic-endocrinology fellowship is integrated with programs at the Walter Reed Hospital and the National Naval Medical Center.

For those selecting clinically oriented fellowships, research experience will be obtained in the Laboratory or Branch of the Fellow's choice from among the Institute's three clinical research Branches and nine basic science Laboratories. For those candidates selecting laboratory research exclusively, these same choices are available.

The major emphasis of the NICHD Intramural Research Program is on basic and clinically applied research in the broad area of developmental biology. Areas presently being examined include developmental endocrinology, reproductive biology, cellular differentiation, human genetics and inborn metabolic errors, molecular endocrinology, developmental and molecular immunity, developmental neurobiology, molecular genetics (bacteria, virus, yeast, drosophila, and animal cell), pharmacogenetics, growth factors, neurochemistry and neuroimmunology, theoretical and physical biology, cell biology (especially receptors and organelles), and comparative ethology.

For physicians interested in pursuing a career in academic medicine and research, these Fellowships offer an opportunity to train with scientists and physicians of international stature. Excellent facilities are available on the 306-acre NIH campus in Bethesda, Maryland, including a 480-bed research and teaching hospital, more than 1,000 laboratories, and the National Library of Medicine. Medical Staff Fellows receive an initial salary of $30,000 with increments of $2,000 per year. Moving and traveling allowances, and Federal health care benefits are available.

Interested candidates should send their curriculum vitae to (or request further information from):

Arthur S. Levine, M.D., Scientific Director,
National Institute of Child Health and Human Development,
National Institutes of Health, 9000 Rockville Pike,
Building 31, Room 2A50, Bethesda, Maryland 20892, (301) 496-2133

NIH is an Equal Opportunity Employer.

Deadline for applications is November 15, 1987.

NATIONAL INSTITUTES OF HEALTH

MOSBY Medical Journals

SAMPLE COPIES of journals are available.

- **THE JOURNAL *of* ALLERGY *and* CLINICAL IMMUNOLOGY**
  Monthly. Institutions: $92.00; Individuals: $45.00; Students, residents: $32.00. Official publication of the American Academy of Allergy and Immunology.

CLINICAL NUTRITION
Bimonthly. Institutions: $39.00; Individuals: $39.00; Students, residents: $21.00.

- **CLINICAL PHARMACOLOGY *and* THERAPEUTICS**
  Monthly. Institutions: $113.00; Individuals: $65.00; Students, residents: $45.00. Official publication of the American Society for Pharmacology and Experimental Therapeutics and the American Society of Clinical Pharmacology and Therapeutics.
- **JOURNAL *of* THE AMERICAN ACADEMY *of* DERMATOLOGY**
  Monthly. Institutions: $104.00; Individuals: $57.00; Students, residents: $36.00. Official publication of the American Academy of Dermatology.
- **THE JOURNAL *of* HAND SURGERY (American Volume)**
  Bimonthly. Institutions: $85.00; Individuals: $38.50; Students, residents: $25.00. Official publication of the American Society for Surgery of the Hand.
- **AMERICAN HEART JOURNAL**
  Monthly. Institutions: $98.00; Individuals: $51.00; Students, residents: $33.00.
- **HEART & LUNG: THE JOURNAL *of* CRITICAL CARE**
  Bimonthly. Institutions: $68.00; Individuals: $21.00; Students, residents: $16.00.
- **AMERICAN JOURNAL *of* INFECTION CONTROL**
  Bimonthly. Institutions: $66.00; Individuals: $19.75; Students, residents: $15.00. Official publication of the Association for Practitioners in Infection Control.
- **THE JOURNAL *of* LABORATORY *and* CLINICAL MEDICINE**
  Monthly. Institutions: $109.00; Individuals: $62.00; Students, residents: $35.00. Official publication of the Central Society for Clinical Research.
- **AMERICAN JOURNAL *of* OBSTETRICS *and* GYNECOLOGY**
  Monthly. Institutions: $102.00; Individuals: $59.50; Students, residents: $40.00. Official publication of the American Board of Obstetrics and Gynecology, The American Gynecological and Obstetrical Society, plus 32 regional societies.
- **OTOLARYNGOLOGY—HEAD *and* NECK SURGERY**
  Monthly. Institutions: $115.00; Individuals: $70.00; Students, residents (non-Academy members): $45.00; Residents (Academy members): $20.00. Official publication of the American Academy of Otolaryngology–Head and Neck Surgery, the American Academy of Otolaryngic Allergy, and the American Neurotology Society.
- **THE JOURNAL *of* PEDIATRICS**
  Monthly. Institutions: $95.00; Individuals: $47.50; Students, residents: $30.00.
- **SURGERY**
  Monthly. Institutions: $97.00; Individuals: $49.50; Students, residents: $32.00. Official publication of the Society of University Surgeons, Central Surgical Association, and the American Association of Endocrine Surgeons.
- **THE JOURNAL *of* THORACIC *and* CARDIOVASCULAR SURGERY**
  Monthly. Institutions: $118.00; Individuals: $70.00; Students, residents: $45.00. Official publication of the American Association for Thoracic Surgery and the Western Thoracic Surgical Association.
- **JOURNAL *of* VASCULAR SURGERY**
  Monthly. Institutions: $98.00; Individuals: $57.00; Students, residents: $35.00. Official publication of the Society for Vascular Surgery and the International Society for Cardiovascular Surgery (North American Chapter).

new **THE JOURNAL *of* HEART TRANSPLANTATION**
Bimonthly. Institutions: $60.00; Individuals: $40.00; Students, residents: $25.00. Official publication of the International Society for Heart Transplantation.

- **Included in Index Medicus**

Subscription rates quoted are for USA only. International rates (surface and airmail delivery) available upon request. All subscriptions are for one-year terms. Subscriptions may begin at any time.

A Tradition of Publishing Excellence

Here's what MOSBY'S BOUND VOLUMES can add to your practice!

MOSBY
TIMES MIRROR

Handsomely bound in durable buckram with rich gold stamping, bound journal reference volumes are important to every successful practice.

- gives quick and easy access to important journal articles
- eliminates problems with missing issues or pages
- makes your regular subscription a "working" copy to mark up, tear from, or file
- offers an inexpensive and easy way to guarantee bound reference volumes—prices include shipping

You Must Order Now!
Bound volumes are made up from over-run copies of each journal issue. You never worry about sending out your personal copies. But over-run quantities are limited. We need your order today! Bound volumes are only available to current subscribers and may not be ordered in place of a regular journal subscription. Payment must accompany your order.

Credit Card Orders In The U.S. Call FREE:

gainst the *B. fragilis* group?

94%

Mefoxin

active against 94% of isolates

the facts *still* favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus.*

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986,* Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST II reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage™ # vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

Innovation Plus Expertise!

COMPREHENSIVE GYNECOLOGY

By William Droegemueller, M.D.; Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; and Morton A. Stenchever, M.D.

Innovative enough to emphasize the psychosocial treatment of your patient, with the expertise to cover a full range of diseases and physical problems — this combination brings you the first, all new comprehensive gynecology text in years! Comprehensive discussions on:

- the most current treatments available
- psychosocial approaches to the troubled patient
- family planning and pregnancy termination
- breast disease and sexually transmitted diseases, including AIDS in women
- rape, incest and other physical abuse

The Key Terms and Definitions that begin each chapter and the synopsis of Key Points at the end provide a quick review. Sophisticated graphics highlight pertinent data. Written by four well-known specialists who share their experience and expertise, COMPREHENSIVE GYNECOLOGY presents state-of-the-art information you'll refer to again and again.

July, 1987. Approx. 1,000 pages with 800 illustrations. (Book Code: 01929) About $60.00 (U.S.); $82.95 (Can.)

Risk scoring for preterm labor: Where do we go from here?

Denise M. Main, M.D., and Steven G. Gabbe, M.D.

Philadelphia, Pennsylvania

Risk scoring systems based on traditional demographic, social, and medical factors have limited use, especially in certain populations. Newer approaches, including frequent cervical examinations, periodic outpatient monitoring for contractions, extensive daily monitoring at home for contractions in very high-risk persons, and identification and reduction of modifiable behavioral risks, offer promise. (AM J OBSTET GYNECOL 1987;157:789-93.)

Key words: Risk assessment for preterm birth

Enthusiasm for risk scoring systems based primarily on traditional epidemiologic and medical factors to predict spontaneous preterm birth peaked in the 1970s and early 1980s. It was widely assumed that scoring systems could be developed that would effectively identify women at increased risk for spontaneous preterm delivery. Specific interventions designed to diagnose preterm labor early could then be selectively applied to women identified as at high risk.

Established risk scoring indexes

Five risk scoring systems have been developed to predict spontaneous preterm birth[1-7] (Tables I and II). Although varying in detail, these systems consist of selected social and demographic factors, past obstetric and medical history, and in some cases current pregnancy complications. The most widely used system is that developed by Papiernik and modified by Creasy. It is easy to apply, specific in its goal to identify women at high risk for spontaneous preterm birth, and has performed better than other scores in prospective studies. Thirteen percent of a population screened in New Zealand were determined to be at high risk. These women had a 30% chance of delivering preterm infants (positive predictive value) and accounted for 64% of all the spontaneous preterm births in the population. The sensitivity of the screen was much higher for multigravidas than for primigravidas (77% versus 31%). This screen has performed less well in United States samples.[5,6]

From the Jerrold R. Golding Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Pennsylvania School of Medicine.

Reprint requests: Denise M. Main, M.D., Department of Obstetrics, Gynecology and Reproductive Sciences, Room M-1489, University of California, San Francisco, San Francisco, CA 94143.

Limitations of established risk scoring systems

One of the major limitations of these risk assessment tools results from our relative ignorance about the pathophysiology of preterm labor and premature rupture of the membranes. Multiple factors contribute to these common outcomes. It is unlikely that traditional risk factors can achieve useful specificity and sensitivity in predicting some causes such as abruptio placentae or genital tract infections. In the best situation, the risk scoring indexes identify two thirds of the women who experience preterm birth. Some factors that appear to be very predictive, such as diethylstilbestrol exposure or uterine malformation, occur very infrequently and hence have low attributable risk within a population. In contrast, other factors such as smoking, which as an individual risk factor is a weak predictor, assume a high attributable risk because of its high prevalence.

Most of the factors included in the risk assessment indexes have been known to be associated with preterm birth and low birth weight for at least 20 years. Many factors, such as age, race, and socioeconomic status, do not cause preterm birth directly, and the mediating factors that lead to actual preterm delivery are poorly

Table I. Risk scoring indexes designed to predict preterm birth

Study and yr	*Adverse outcome measured*	*Screening system*	*Time of screening*	*Population*
Nesbitt and Aubry, 1969	PTB 21-37 wk	Own system designed to predict a variety of adverse pregnancy outcomes	First prenatal visit	969 clinic patients, N. Y. State, two thirds white, one third black
Kaminski et al., 1973	PTB <36 wk	PPRS	First trimester	Married multiparous French women with singleton pregnancies
Akhtar and Sehgal, 1980	PTB 21-36 wk	Own system designed to predict a variety of adverse pregnancy outcomes	Initial clinic visit updated at delivery	Rural, medically indigent, primarily white women in W. Va.
Creasy et al., 1980	Spontaneous PTB 20-37 wk	Modified PPRS	Initial screen at first visit, rescreened 26-28 wk	New Zealand hospital population 28% primigravid
Herron et al., 1982	PTL	Modified PPRS	Initial and follow-up screen 26-28 wk	Predominantly white middle-class in San Francisco
Main et al., 1987	All PTB 30-37 wk Spontaneous PTB 20-37 wk	Modified PPRS	Single screen <18 wk	Black Inner City women in Philadelphia
Ross et al., 1986	Spontaneous PTB 20-37 wk	Simplified problem-oriented perinatal risk assessment system	Retrospective review	Women in Los Angeles, predominantly Hispanic

PPRS, Papiernik prematurity risk score; PTB, preterm birth; PTL, preterm labor.

understood. Furthermore, most of the risks, including the demographic factors previously cited, uterine malformations, multiple gestation, and prior medical and obstetric history, cannot be changed by the person at risk or by health care providers.

Another limitation of these risk assessment tools is inherent in screening tools in general. High sensitivity is desired when the outcome predicted is very serious but is usually accompanied by lowered specificity and lowered positive predictive values. The incorrect identification of women with normal outcomes as high risk increases the emotional burden for these women and greatly increases the cost of additional medical interventions. The positive predictive value also depends on the prevalence of the adverse outcome in the population studied. In populations in which the outcome is common, the true-positive rate should increase, and the false-positive rate should be lower. False positives are more common when the outcome occurs infrequently, as observed by Herron et al.[2, 5] when they applied the scoring index to a group of predominantly white, middle-class women in San Francisco, a population with a preterm labor rate of 4.7%. In this prematurity prevention study, the sensitivity and specificity of the screening tool were only slightly less than that achieved in New Zealand. However, the positive predictive value was considerably lower. Only one of every six women identified as high risk experienced preterm labor.

We recently applied the same scoring system once to a group of 391 black, inner city women registered for prenatal care before 18 weeks' gestation. These women, who have a high baseline preterm delivery rate, received no special intervention to prevent preterm birth and were not aware of their risk status.[6] In this sample, the scoring system failed to distinguish effectively women who delivered before term from those who delivered at term. Women scoring ≥10 points (that is, high risk) had an 18% preterm delivery rate, whereas those scoring <10 points had a 14% preterm delivery rate. The sensitivity and specificity were similar for multiparous and primiparous women (28% versus 23% and 78% versus 82%, respectively). Adjusting the cut-off score and reweighting factors with discriminant analysis did not improve the predictive value of the scoring system. Analysis of an additional 60 social, demographic, and medical factors also failed to produce a useful risk assessment tool.

How can we explain the very different use of a scoring system in one population compared with another? First, the most predictive risk factors may be more prevalent in one population. Second, the scoring system may achieve much of its sensitivity from distinguishing between socioeconomic groups, a factor not considered in our universally low-income group. Alternatively, the significance of a particular risk factor may vary among populations. It is of interest that Rush[8] and co-workers found that the history of a prior low birth weight delivery was a much stronger predictor of repeat low birth

weight deliveries in white as opposed to black women. This discrepancy suggested to these authors that "with lower social status, fewer of the poor outcomes are caused by inherent physiological problems and more by adverse environmental conditions which would be less likely to be held constant between pregnancies." In addition, the relative contribution of the proximate causes for spontaneous preterm birth, namely, preterm labor and premature rupture of the membranes, may vary. This was recently well demonstrated by Meis et al.[9] Using two samples of approximately 1500 women each, one group receiving public medical assistance and one group with private insurance, they showed significant differences in proximate factors. In the public assistance group, 34% of preterm births were caused by preterm labor, 46% by premature rupture of the membranes, and 20% by medical complications. In contrast, in the private insurance group, 55% of preterm births resulted from preterm labor, 27% from premature rupture of the membranes, and 18% from medical complications. Specific risk factors may more strongly predict preterm labor rather than premature rupture of the membranes, although we were unable to demonstrate this in our relatively small sample. Finally, Creasy et al.[4] and Herron et al.[5] found that rescoring women in the second trimester, including specific pregnancy complications such as multiple gestation, bleeding, and cervical dilation, improved sensitivity.

Newer approaches to risk assessment

It has become apparent that three more specific approaches may be useful. First, cervical examinations and intermittent monitoring for contractions may more effectively identify women at risk for preterm labor. Second, a few risk factors appear sufficiently predictive to warrant more intensive evaluation during pregnancy, including daily medical contact and/or monitoring for uterine contractions. Third, some of the behavioral risk factors associated with preterm birth may be modified in pregnancy with improved outcome.

Risk assessment by cervical examination and assessment of uterine contractility. The association of cervical dilation in the late second and third trimesters with preterm labor has been emphasized by Papiernik and other European investigators. In a series of 4330 women examined at least once before 37 weeks' gestation, the relative risk for preterm delivery was approximately four times greater if the internal os was opened 1 cm or more.[10] Almost one quarter of the 4.4% of this population found to have cervical dilation between 25 and 28 weeks' gestation experienced preterm birth. This study was undertaken as part of a complex and successful intervention program to prevent preterm births. Therefore one can speculate that even higher rates of preterm births might have occurred in women with cervical change had interventions not been undertaken. Indeed, in a smaller, blinded, noninter-

vention study, Leveno et al.[11] studied the predictive value of a single cervical examination between 26 and 30 weeks' gestation. Cervical dilation of at least 2 cm was observed in 8% of the 185 women studied. Four of the seven low birth weight deliveries occurred in these 15 women.

Detection of increased uterine activity may best identify women with higher risks of preterm labor. We[12] monitored 148 black Inner City women for 1 hour on a weekly to biweekly basis between 27 and 34 weeks' gestation using a portable tocodynamometer. The study was completely blinded. All women had singleton pregnancies and had no history of preterm labor or delivery. The use of ⩾6 contractions per hour on at least one occasion between 28 and 32 weeks' gestation as a marker for excessive uterine activity would have identified 76% of the women who experienced preterm labor. Women so identified as at high risk had a 27% chance of developing preterm labor.

Daily home monitoring of uterine activity. An increased frequency of uterine contractions as assessed by daily home tocodynamometry appears to distinguish between high-risk women who develop preterm labor and those who do not.[13] Women included in studies that use ambulatory home monitoring have had very specific risks such as multiple gestation, uterine malformation, and repetitive preterm birth. At least one third of women so selected will develop preterm labor. In a recent randomized controlled study of very high-risk patients, Morrison et al.[14] were able to diagnose preterm labor earlier and significantly prolong gestation in 34 women monitored daily at home. The 33 control women were taught to identify the early signs of preterm labor and were contacted by telephone twice weekly by a nurse to assess their status. Two thirds of the women in each group experienced preterm labor. Although very exciting, such an intensive approach should be limited currently to women with select specific risks for preterm labor or women who have already experienced preterm labor in the current pregnancy. Further research is needed to confirm the efficacy of this approach in other high-risk patients and identify the components of this monitoring system that are most important.

Modification of behavioral risk factors for preterm birth. Our proposals are based on another approach, the aim of which is to define predictive factors which *can be modified during pregnancy*, or which lead to preventive action. Our hypothesis is that if positive and lasting changes are made in the habits of pregnant women, this can lead to a reduction in preterm birth rates *(emphasis added).*

E. Papiernik
Clinics in Obstetrics and Gynaecology
(London) (1984;11:815.)

At least five behavioral risk factors which may be associated with preterm birth could be modified in pregnancy. They include smoking, poor weight gain during pregnancy, absent or inadequate prenatal care, heavy physical labor, and psychological stress. Relatively few studies, however, have been designed to evaluate the effects of modifying these behaviors during pregnancy.

Interestingly, Papiernik et al.[15] attribute most of the overall reduction in preterm births in Haguenau, France, to reduction in preterm births among low- and medium-risk women rather than among women with classic risk factors such as prior preterm births or bleeding during pregnancy. The main intervention for these women was a careful analysis of their physical activity and recommendations to decrease hard physical labor. The French government supported compensation during periods of unemployment. However, most other studies have not associated preterm birth with paid employment or physical activity. Thus more research is needed that links excessive uterine contractility to heavy physical activity in low-risk women before widespread reduction in physical activity during pregnancy can be recommended.

Sexton and Hebel[16] have demonstrated in a prospective, randomized, and controlled trial that pregnant smokers who participated in an individualized smoking cessation project more often stopped smoking and as a group were delivered of significantly heavier babies than were control patients. These impressive results were obtained even though only one out of three women who still smoked at the time of enrollment into the study quit smoking during pregnancy. There was no effect on gestational age. Further research is needed regarding effective means to promote smoking cessation, reduction of other substance abuse, improved nutritional practices, and more complete health care access. Better understanding of attitudes toward pregnancy, health care beliefs, and daily habits and stresses of pregnant women with diverse backgrounds will facilitate such intervention programs.

Comment

Traditional risk scoring indexes may be of benefit in select populations. Persons using such scoring systems, however, should demonstrate that they can effectively identify high-risk women within their population. One cannot concurrently test a scoring system and an intervention program in the same group of patients. Effective interventions may mask the predictive value of the scoring system.

Careful assessment of uterine contractility and cervical change in unselected women may improve both our ability to identify women at high risk for preterm birth and our understanding of the mechanisms lead-

ing to preterm labor and premature rupture of the membranes. Accurate daily ambulatory tocodynamometry appears to have clinical value in very high-risk patients.

Emphasis on risk factors that can be modified during pregnancy may have the greatest success in decreasing the incidence of preterm birth in women without classic medical or historical risk factors. It is clear that programs to modify women's habits during pregnancy are difficult and take time to institute.[15] More studies designed to modify behavior by means of clearly defined, limited interventions are needed.

Prophylactic antibiotics for cesarean delivery: A simple cost-effective strategy for prevention of postoperative morbidity

Patrick Duff, M.D.
Tacoma, Washington

Postoperative endomyometritis is the most common complication associated with cesarean delivery. The frequency of endomyometritis varies from 5% to 85% (mean 35% to 40%), depending on the socioeconomic characteristics of the patient population and the indication for abdominal delivery. In women undergoing cesarean section after extended duration of labor and ruptured membranes, the use of prophylactic antibiotics has been consistently effective in decreasing the frequency of endomyometritis. A single dose of antibiotic administered after the umbilical cord is clamped provides a degree of prophylaxis comparable to that achieved with two- and three-dose regimens. There is no evidence that the newer extended-spectrum cephalosporins or penicillins are better for prophylaxis than ampicillin or a first-generation cephalosporin. Administration of antibiotics by intraoperative irrigation is an acceptable, but not superior, alternative to systemic antibiotic administration. Prophylactic antibiotics alter the vaginal flora after operation, but to date harmful clinical effects have not occurred as a result of such alteration. (Am J Obstet Gynecol 1987;157:794-8.)

Key words: Cesarean delivery, antibiotic prophylaxis

The most common complication associated with cesarean delivery is endomyometritis. The frequency of infection varies from 5% to 85%, with a mean incidence of 35% to 40% in most studies.[1,2] In general, the highest incidence of infection occurs in indigent women having cesarean delivery after extended duration of labor and ruptured membranes. Many investigations have demonstrated that prophylactic antibiotics are effective in decreasing the frequency of post–cesarean section endomyometritis in women having unscheduled abdominal delivery. However, some controversy still exists about which antibiotics should be used for prophylaxis, duration of use and in what manner they should be administered. The purpose of this article is to present a simple, cost-effective plan for utilization of prophylactic antibiotics in women having cesarean delivery.

Criteria for use of prophylactic antibiotics

Three clinical criteria should be fulfilled to justify perioperative use of prophylactic antibiotics. The surgical procedure, by necessity, must be performed through a contaminated operative field. There must be a high incidence of postoperative infection, that is, exceeding 15% to 20%, in the absence of prophylaxis. Finally, there must be serious sequelae that may result from the primary infection.

From the Division of Maternal-Fetal Medicine, Madigan Army Medical Center.
Reprint requests: Dr. Patrick Duff, Department of the Army, Madigan Army Medical Center, Tacoma, WA 98431.

Unscheduled cesarean delivery clearly fulfills these criteria. The operation inevitably is associated with considerable bacterial contamination of the endometrial and peritoneal cavity. If some form of prophylaxis is not administered, the incidence of post–cesarean section endomyometritis is unacceptably high in most patient populations, averaging 35% to 40%.[2] In patients who have endomyometritis, potentially life-threatening sequelae such as septic shock, pelvic abscess, and septic pelvic vein thrombophlebitis can occur.

Mechanism of action of prophylactic antibiotics

Prophylactic antibiotics appear to act in two principal ways. By destroying some bacteria and slowing the growth of others, they directly decrease the size of the bacterial inoculum at the surgical site. Prophylactic antibiotics also alter the characteristics of the serosanguineous fluid that collects in the pelvic cavity after operation, rendering it less suitable to support the growth of microorganisms. Other possible mechanisms of action include interference with the production of bacterial proteases and interference with attachment of bacteria to mucosal surfaces. In addition, antibiotics may, in a way that is not completely understood, enhance the host's phagocytic capacity.[3]

Burke[3] has demonstrated that the timing of antibiotic delivery to injured tissue is of critical importance in determining the efficacy of prophylaxis. The greatest therapeutic effect occurs when antibiotics are administered just before, or coincident with, the time when

maximal bacterial contamination and tissue trauma occur.

Objectives in the use of prophylactic antibiotics

One major objective in the use of prophylactic antibiotics is reduction in the incidence of endomyometritis. This infection causes the patient considerable discomfort and usually results in increased duration and expense of hospitalization. In addition, it is the usual precursor for such serious complications as pelvic abscess, septic shock, and septic pelvic vein thrombophlebitis. A second objective in the use of prophylaxis is reduction in the incidence of major wound infections. Such disorders usually require a second surgical procedure to open and debride the incision and may result in dehiscence and evisceration. For these reasons, wound infection is even more likely than endomyometritis to result in marked prolongation of the patient's hospitalization. The third theoretical objective in the use of prophylaxis is decrease in the duration and expense of hospitalization. The final objective is prevention of the rare, life-threatening complications of operative site infection.

Results of clinical trials of systemic prophylaxis

To date more than 25 prospective, randomized, placebo-controlled trials of systemic prophylaxis for cesarean delivery have been published.* The most important findings of these studies are summarized below.

1. Virtually without exception, all studies have demonstrated a significant decrease in the frequency of endomyometritis in women having unscheduled abdominal delivery after extended duration of labor and ruptured membranes. The reduction in the incidence of endomyometritis has averaged 50% to 60% in most studies.[2] These data are so convincing that I believe it is not ethical to use placebo controls in future studies of prophylaxis in these high-risk patients.

2. Most investigations have not shown a statistically significant decrease in endomyometritis in women undergoing elective, scheduled abdominal delivery. However, there may be some patient populations in which the underlying frequency of infection is high enough that prophylaxis does have a beneficial effect in reducing the incidence of postoperative morbidity and decreasing the expense of hospitalization.[4]

3. The drugs most frequently used for prophylaxis have been the cephalosporins. Although it is widespread practice in the United States to utilize the newer extended-spectrum cephalosporins for prophylaxis, there is no evidence that these agents are better for this purpose than ampicillin or a first-generation cephalosporin. To date three authors[5-7] specifically have compared limited-spectrum agents to extended-spectrum antibiotics for prophylaxis. In these trials, 312 patients received an extended-spectrum agent and 373 women received a more limited-spectrum agent (Table I). None of the individual trials, nor all considered collectively, has been able to show that the more expensive, extended-spectrum drugs are more effective in decreasing the incidence of postoperative endomyometritis.

4. Most investigators have used a three-dose regimen for prophylaxis. However, there now are at least seven reports demonstrating that a single dose of antibiotic is comparable in efficacy to multidose regimens. Three of these investigations[8-10] compared single doses of antibiotic to placebo. In each instance, patients who received antibiotics fared better than placebo controls and as well as historical controls in other studies that used conventional three-dose regimens for prophylaxis. Three additional studies[11-14] compared a single dose of one drug to three doses of the same drug or another agent. There were no significant differences in treatment effects between the groups.

5. Three investigators[15-17] specifically sought to determine whether an extended course of antibiotics was more effective than limited perioperative prophylaxis in decreasing the incidence of post–cesarean section infection. Elliott et al.[15] demonstrated that a 3-day course of ampicillin was more effective than a three-dose regimen in decreasing the incidence of febrile morbidity and endomyometritis and in shortening the

*A complete list of references is available on request from the author.

duration of hospitalization. However, D'Angelo and Sokol,[16] were unable to confirm a significant difference in the combined incidence of wound infection and endomyometritis when a 5-day course of treatment with cefazolin plus cephalexin was compared with a four-dose course of cefazolin. DePalma et al.[17] studied two drug regimens (cefamandole and penicillin plus gentamicin) and were unable to confirm an advantage for extended early therapy versus limited perioperative prophylaxis. This latter study is noteworthy because the authors' patients were at exceptionally high risk of post–cesarean section infection as a result of their low socioeconomic status and extended duration of labor and ruptured membranes.

At the present time it is not possible to identify precisely that subset of women who are at such high risk of infection that they need early treatment with therapeutic antibiotics rather than simple prophylaxis.[18] Until a laboratory or clinical test with high sensitivity and predictive value is available, extended prophylactic or "early treatment" regimens cannot be recommended.

6. For most surgical procedures, it is desirable to administer prophylactic antibiotics preoperatively before tissue injury and bacterial contamination occur. If this policy were implemented for cesarean delivery, the neonate would be exposed to antibiotic before birth. In theory, even this limited exposure might interfere with the ability of the pediatrician to evaluate the newborn for sepsis. Fortunately, multiple reports now have confirmed that delay in administration of antibiotics until after delivery of the fetus does not diminish the effectiveness of prophylaxis.

7. Most investigators have been unable to demonstrate that antibiotic prophylaxis decreases the incidence of abdominal wound infection. In the studies in which a positive effect was confirmed, the incidence of wound infection in the control population was high, ranging from 7.4% to 16.1%. In the studies that showed no reduction in wound infection, the incidence of infection in the control population was lower, ranging from 0% to 7%. With such a low frequency of infection in the control groups, many of the studies with negative findings may not have had a sufficient sample size to detect a beneficial treatment effect.

8. Use of prophylactic antibiotics has not eliminated completely the occurrence of serious sequelae of postcesarean endomyometritis. Despite receiving prophylaxis, some patients still have septicemia, pelvic abscess, or septic pelvic thrombophlebitis. However, the incidence of such complications is low, even in patients receiving no prophylaxis.[1,2]

9. At present, no serious maternal side effects have occurred as a result of use of antimicrobial prophylaxis for cesarean delivery. There are case reports, however, of at least two deaths from anaphylaxis in patients who received intraoperative injections of cephalothin during nonobstetric surgical procedures.[19] Therefore, the possibility of untoward side effects always must be considered when a decision is made to use prophylactic antibiotics.

10. Several recent investigations[20,21] have shown that changes in the vaginal flora occur in women who receive prophylactic antibiotics at the time of cesarean delivery. The alterations in flora depend on the specific drug selected for prophylaxis and the length of time it is administered.

The clinical significance of these changes in the flora of the lower genital tract is not entirely clear. No investigator yet has documented an increased incidence of more serious complications in women who become infected despite receiving prophylaxis. However, of particular concern is the increased isolation of enterococci in women receiving prophylactic cephalosporins. Many antibiotics used singly or in combination for treatment of postcesarean infection do not provide effective coverage against enterococci. Therefore, if prophylactic antibiotics are to be used routinely on an obstetric service, careful surveillance must be maintained to detect unusual changes in antimicrobial susceptibilities.

There are three principal components of an effective surveillance system. First, genital tract cultures should be performed in all patients who become infected despite receiving prophylaxis. The antibiotic susceptibility patterns of bacteria isolated from these patients should be evaluated to determine whether selection of resistant microorganisms is occurring. Second, the clinical course of these women should be monitored to determine whether they are experiencing a suboptimal response to the usual antibiotic regimens selected for treatment of postoperative infection. Finally, the hospital laboratory should conduct a periodic review of the susceptibility patterns of commonly isolated microorganisms to detect gradual changes in antimicrobial resistance throughout the hospital.

Intraoperative antibiotic irrigation

Intraoperative antibiotic irrigation appears to exert its primary effect by providing a high concentration of antibiotic directly to the site of injured tissue and the site of maximum bacterial contamination. Systemic absorption of antibiotic occurs with topical irrigation, however, especially when both intrauterine and intraperitoneal irrigation is performed.[21] Serum concentrations of antibiotics, in fact, may exceed the minimal inhibitory concentrations for many genital tract pathogens. Therefore, the mechanism of action of intraoperative irrigation appears to be due, at least in part, to systemic absorption of antibiotic and not exclusively to a local effect on the endometrium.

There now are more than 10 studies of intraoperative irrigation for cesarean delivery.* The principal findings of these investigations are summarized below.

1. Most of the studies have shown that antibiotic irrigation is superior to placebo or saline irrigation.

2. Unlike systemic prophylaxis, not all antibiotics have been equally effective when administered by irrigation. The observed differences in treatment effect appear to be partially due to differences in irrigation techniques. For example, there are differences between the volume of diluent, and hence the concentration of antibiotic, used in different studies. Some authors have irrigated both the uterine and peritoneal cavity; others have irrigated only the former. Some investigators have allowed the irrigant solution to remain in the uterus and peritoneal cavity, whereas others have immediately aspirated the solution. Differences in the pharmacokinetic properties of the drugs, particularly in half-life of the antibiotic in serum and tissue, also may be important in explaining the varied results of these studies. On the basis of information presently available, cefamandole appears to be the agent with the most thoroughly documented evidence of efficacy.

3. Most of the studies that have compared intraoperative irrigation to systemic prophylaxis have used three doses for systemic administration and one dose for irrigation. In a comparison of this nature, there would appear to be a distinct cost advantage for irrigation versus systemic administration. However, recent reports[8-14] have shown that a single dose of systemic prophylaxis can be just as effective and economical as a single dose of drug administered by irrigation.

In view of these latter findings, the principal argument in favor of irrigation is that it minimizes systemic absorption of antibiotic and hopefully reduces the risk of an untoward drug effect. Conversely, the major advantage of systemic prophylaxis is that it is a simpler and less time-consuming method of antibiotic administration.

4. Use of systemic antibiotics in conjunction with intraoperative irrigation does not enhance the effectiveness of prophylaxis.[23] Therefore, there is no justification for combining both methods.

Cost considerations

As outlined, the use of prophylactic antibiotics clearly is effective in decreasing the frequency of postcesarean endomyometritis. This certainly is an important accomplishment from the perspective of the individual patient. In addition, it is a significant achievement from the perspective of the entire health care industry because of issues related to hospitalization cost.

*A complete list of references is available on request from the author.

Consider a hypothetical cohort of 100 high-risk women undergoing cesarean delivery. Let us assume that, in the absence of prophylaxis, endomyometritis develops in 40 patients. It would be reasonable to expect that prophylaxis would decrease the incidence of infection by 50%. Therefore, failure to use prophylaxis results in 20 unnecessary infections.

Let us now consider the cost of treating these 20 patients. The usual parenteral antibiotic regimens used at this institution for treatment of endomyometritis are mezlocillin (3 to 4 gm every 6 hours) or clindamycin (900 mg every 8 hours) plus gentamicin (1.5 mg/kg every 8 hours). Treatment usually is required for a minimum of 4 days. The total wholesale cost for either of these antibiotic regimens is approximately $140. Thus the total cost of treating 20 infected patients would be $2800. Infected patients typically remain hospitalized for 2 days longer than uninfected women, and the hospital's unit charge per patient is $441 per day. Therefore, the added cost for extended hospitalization of the 20 patients is $17,640. These, of course, are minimum estimates because they do not include any added pharmacy charges or incidental expenses that result when a patient has a protracted febrile course.

Balanced against these charges is the cost of the antibiotic selected for prophylaxis. As outlined earlier, the most reasonable choice for prophylaxis would appear to be a single 2 gm dose of a first-generation cephalosporin, such as cefazolin or ampicillin. The costs of these drugs at this hospital are $6.00 and $3.00, respectively. The total cost of administering 100 doses of prophylaxis would be $600 and $300, respectively. Therefore, the net cost savings resulting from use of either of these prophylactic regimens is approximately $17,000 for every 100 surgical procedures. Even if two-dose courses of prophylaxis were used, the savings in costs exceeds $16,000 per 100 procedures. At this institution, approximately 200 unscheduled cesarean deliveries are performed each year, thereby resulting in a minimal savings of at least $32,000 per year.

In patient populations with a lower baseline frequency of infection than noted herein, the savings in cost will be less. Routine use of multidose regimens of the more expensive extended-spectrum agents also will reduce the favorable economic impact of prophylaxis.

Conclusions

Prophylaxis should be used in all women who are in labor or who have ruptured membranes.

Prophylaxis also should be considered in women having elective repeat cesarean delivery if the baseline frequency of endomyometritis or wound infection is unusually high. If the combined incidence of these two infections is in the range of 15% to 20%, use of pro-

phylaxis may have a beneficial effect in reducing morbidity and hospital expense.

For systemic prophylaxis, a single dose of ampicillin (2 gm) or a first-generation cephalosporin such as cefazolin (2 gm) should be administered after the infant is delivered. A second dose of antibiotic should be used only if the operation is prolonged for more than approximately 90 minutes. The rationale for administration of a second dose of antibiotic is that extended operations are likely to be associated with greater bacterial contamination and tissue injury.[3] The second dose of drug should be administered 3 to 4 hours after the first dose.

Use of extended-spectrum cephalosporins or penicillins for prophylaxis should be avoided unless future investigations are able to confirm a decided advantage for the more expensive agents. Indiscriminate use of these drugs for prophylaxis may limit their usefulness in treatment of established infections.

Intraoperative irrigation is an acceptable, but not superior, alternative to systemic prophylaxis. Combining irrigation with systemic administration does not enhance the effectiveness of prophylaxis. Cefamandole is the agent that has been the most extensively tested for irrigation.

When antibiotic prophylaxis is used routinely on an obstetric service, the antimicrobial susceptibility patterns of bacteria isolated from infected patients should be analyzed carefully to detect the emergence of drug-resistant microorganisms and the occurrence of serious infections.

Presidential address of Association of Professors of Gynecology and Obstetrics

Allan B. Weingold, M.D.
Washington, D. C.

It is a significant honor to be recognized by one's peers and to be given the opportunity to lead an organization whose primary goal is the perpetuation of our discipline. It is a particular honor to serve in that role in the twenty-fifth anniversary year of the Association of Professors of Gynecology and Obstetrics, which also represents for me a twenty-fifth anniversary in academic medicine. The goals of my presidential address are limited and simple: to express some aspects of personal philosophy; to summarize the problems we face in medicine, in academic careers, and in our discipline; to review the changes in the Association of Professors of Gynecology and Obstetrics and our specialty in the past 25 years; and to provide some inspirational thoughts about the future.

Persons in my position have a problem. While we are medical teachers in that we have taught students for 25 or more years, we are not experts in education. Although we cannot explain it in educational terms, we have developed an instinct for those approaches in medical education that work and those that do not. It is this instinct that makes some of us react so negatively to the suggestions of those who work in the theory rather than the practice of medical education. For example, the concept that in an ideal world, medical education would be a totally integrated and interdisciplinary experience is one that I do not find very convincing. In my experience, integrated teaching is difficult to plan and to mount, expensive, and extremely time-consuming for the organizers, and it is confusing for the students who have to grapple simultaneously with the different approaches of a variety of persons and disciplines. Of more importance, it is potentially harmful for departments, since it eliminates their strongest stimulus—the responsibility for their own teaching.

Another currently popular concept is that "students should be taught principles rather than facts".[1] The truth is that both are needed. Principles are pretty dull unless the facts that they tie together are known. It is not exciting to have a solution without a problem. Principles are really exciting only when they help us fit together the various bits of knowledge and experience that float about in our heads and make the whole into an attractive story.

We are also told that students should not be taught; it makes them mentally lazy. They should discover their own areas of ignorance and respond appropriately. Perhaps the reason that I find this so hard to accept is my enormous sense of debt and gratitude to the excellent faculty who shared with me the wisdom they had built up through years of experience. I do not think it made me mentally lazy; in fact, I think it opened my mind to all forms of curiosity and adventure. I really enjoy listening to someone who knows his or her subject intimately—and loves it. That teacher can give a particular insight as to how the mind works and what the subject is really about.

Let me now review some of the problems that face us in 1987. After World War II biomedical science was able to achieve major advances in the relief of suffering, the rehabilitation of injuries and the prevention of disease and premature death. This success led to an increased demand for medical services and resulted in a perceived shortage of physician manpower. By 1962, the first year of the Association of Professors of Gynecology and Obstetrics, this country was prepared to

mobilize for a substantial expansion of its capacity to train health professionals. Academic medical centers produced and applied much of the new biomedical knowledge and helped, in a major way, to fulfill society's medical commitments to its indigent members. In 1987 it appears that society sees a physician glut and has recognized the limits of its ability, or at least its willingness, to accord a protective status to these institutions. Efforts to curb escalating expenditures for the care of elderly persons and indigent persons have resulted in new payment systems that are designed to foster price competition and to eliminate hidden subsidies for teaching institutions.[2]

The primary environmental change affecting medical education is an economic one. Teaching hospitals are motivated to cut expenses, increase efficiency, and be more businesslike. Because of decreasing support for research and reduced funding in support of medical education, medical schools are encouraging faculty members to supplement their salaries by an increase in the number of patients they treat.

Large-scale purchasers of medical services are seeking to contract with hospitals and physician groups that will provide acceptable quality of services at the lowest cost. These purchasers do not believe that educational costs are their responsibility. The implications for the academic medical centers are ominous inasmuch as they also provide a disproportionately large share of the most sophisticated, intensive, and expensive hospital services. In particular this care is provided to medically indigent persons. Six percent of these hospitals provided 47% of the charity care charges and incurred 35% of the bad debts in the country.[2] Obstetric care alone accounted for nearly 25% of all uncompensated hospital charges. In 1983, this amount was $1.7 billion. Regionalization of perinatal care (at least as it involves the medically insured patient) is more difficult because hospitals are encouraged to compete rather than cooperate.

Teaching services are having difficulty in the maintenance of the patient base necessary for their mission inasmuch as well-trained alumni now provide, in community hospitals, specialized services that were available earlier only at academic medical centers. What we, in the academic medical center, produce is a valued commodity, with no proprietary rights to it. It is different from inventing an item at Bell Laboratories, which the company markets and benefits are reaped for 17 years.[3] Our product, the student, resident, fellow, or the results of research, is rapidly translated to patient care in a variety of settings, often to the detriment of the medical center.

In addition, the experience students and residents receive on a tertiary in-patient service is composed of chronic and complex care and is generally not related to situations that they will face in practice. Increasingly, with same-day admissions and early discharge, they do not get to see the entire span of medical events. The obvious solution, the development of large affiliated programs with a community hospital base, goes a long way toward solving the numbers problem in student and resident training, but it also disperses and dilutes the educational effort and the continuity of care that is possible in a single-unit health center.

And what of the product of our efforts? Students and residents have always been anxious about beginning their medical careers, but these concerns focused more on quality-of-living issues and practice environment. These have been replaced by some very real issues, such as fears of a surplus of physicians, the prospect of competing with professional colleagues and former classmates, the decline of the traditional, solo fee-for-service medical practice, the loss of autonomy from health care institutions, government, and third-party payors, and the impact of technological change.[4]

Although there has been no perceptible decline in the quality of the credentials presented by applicants entering medical school, the number of applicants has decreased steadily since 1974 and a decline in the quality of the applicant pool should be anticipated.

At times like this all of us need to step back from these problems and look for some perspective in dealing with them on the basis of where we have been. I would like to look at "APGO at 25" to remind all of us of the enormous changes that have occurred since the founding of this society.

Table II. Changes in field of health care

	Then	*Now*
National health expenditures	$26.5 billion	$381.2 billion
Percentage research-development	4.8%	3.0%
Total number of physicians	274,000	486,000
Obstetrician-gynecologists	14,000	34,000
U.S. medical schools	86	127
Applicants	15,740	29,000 (1975 peak 42,000)
Women applicants	8.1%	35.2%
Graduates	7,480	16,875
Education expenditures	$436 million	$9,000 million
Federal funding	48.1%	23.5%
Physician's services for funding	6.0%	35.9%
Tuition		
State (mean)	$498	$3,959
Private (mean)	$1,050	$13,105
Full-time clinical faculty	8,750	45,300
Postgraduate salary (1 yr)	$2,465	$21,800
Postgraduate women (1 yr)	8%	51%
Malpractice premium (Washington, D.C.)	$640	$58,000

The first meeting of the Association of Professors of Gynecology and Obstetrics was held at the Pick-Congress Hotel in Chicago in 1962, with 175 people in attendance under the leadership of the first president, Roy Holly, M.D. The first five programs focused entirely on curriculum, evaluation, and pedagogy in undergraduate and graduate education. Inevitably, thereafter, the problems of the real world intruded into the program (Table I). These problems have dramatically changed the face of the entire educational enterprise during the past 25 years. Some of these changes are depicted in Table II. The focal points include the real as well as inflationary increases in both total national health costs and the costs of medical education; the increase in the number of medical schools, medical students, clinical faculty, practicing physicians, and specialists in obstetrics and gynecology; the women's movement, with its major impact on medical education; and the steadily decreasing component of educational costs funded by the federal government.

From a historical perspective, it is also important to remember that many of these changes occurred in response to predicted needs that were perceived as largely unmet 25 years ago. The accuracy of our predictions was not high. "The Census Bureau projection of 6,400,000 births in 1985 bears specifically on the need for more maternity beds and more medical manpower in this specialty."[5] The actual number of births in 1985 was 3,747,000. There have been many changes in our discipline in this relatively short time span. "Since there is such a small chance of the survival of an infant under 1,000 gms., (less than 5%), all such fetuses should be classified as abortuses."[5] Also a word of caution about the excesses of operative delivery when the national cesarean section rate had climbed to 4.8%: "There was a time when the excellence of an obstetric service was judged by the scarcity of cesarean sections performed. There has been a tremendous shift in viewpoint regarding the validity of this criterion resulting in the current increased rates."[5] One needs only to reflect on the fact that none of the techniques, therapies, or clinical diagnoses depicted in Table III were clinically relevant 25 years ago.

Table III. Innovations and areas of concern in obstetrics-gynecology since 1962

Danocrine
Surrogates
Fetal monitoring

Accurate assessments of the future for today's students do not exist because of the difficulty of predicting changes in health care utilization, technology, and patterns of care provision. The changing environment of medicine presents both threats and opportunities for young physicians. The very nature of technological progress makes the role of technology less certain. Some advances may reduce the demand for the services of a particular specialty if the technology can be used

by nonphysicians. Others may require more physician involvement because of the need for professional sophistication in their use.[4] Other advances transform the very nature of a specialty inasmuch as we are now seeing the so-called noninvasive cardiologic techniques impacting on the field of cardiovascular surgery. In turn, magnetic resonance imaging, by accurately visualizing coronary artery occlusions, could obviate catheterization skills learned in current cardiology fellowships. This is a form of technological vulnerability.

The demographics of health care are changing. Visits to the physician increase as the patient ages. Women, after the age of 17, consistently have a greater number of visits to the physician per year. In a population that is rapidly aging and one in which women will make up a decided majority of elderly persons, these trends will strongly influence the nature of our practices and how we train for the specialty. The changing structure of health care is already visible in a variety of "turf disputes" resulting in a decline of collegiality within the physician community.[6]

Pressure will increase to limit the growth in physician supply from both within and outside the profession. Reduction in the size of medical school classes, in the face of significant fixed costs, is not associated with a parallel decrease in the cost of education. Smaller class sizes will inevitably result in higher tuitions; this will further discourage economically disadvantaged students from applying for admission to medical school. Closing medical schools is a solution, but the list of volunteers is small. There will also be a move to reduce the number of graduate medical education training positions. This will intensify the competition for residents' positions.

Despite all these potentially adverse consequences to individual physicians, I believe that innovations in medical education, technology, and the organization of medical practice will continue to improve the ability of physicians to provide high-quality medical care to their patients. After years of change driven by biomedical discoveries emanating from the academic medical centers, there is a new site of innovation within the delivery system itself and those in the forefront are not academicians.[4] It is important that, as we translated what we have learned in the laboratory to the delivery system in the past, we must now take what is being learned in the marketplace and bring it back to the classroom.

Each physician must understand the changing horizon of medicine and be able to take whatever steps are necessary to remain professionally flexible. This capacity needs to be taught. The challenge lies with those of us who teach our specialty to demonstrate that flexibility and to identify and train the leaders for the future of medical practice from among the current medical students.

A sonographic screening method for Down syndrome

C. Lockwood, M.D., B. Benacerraf, M.D., A. Krinsky, M.D., K. Blakemore, M.D., K. Belanger, Ph.D., M. Mahoney, M.D., and J. Hobbins, M.D.

New Haven, Connecticut, and Boston, Massachusetts

We describe a potential screening method for the second trimester detection of the fetus with Down syndrome by the use of standard sonographic biometry. Retrospective assessment of the biparietal diameter, femur length, and biparietal diameter/femur length ratio in 55 fetuses with Down syndrome and 544 control fetuses was performed at two medical centers. Adequate numbers of cases and controls were available to permit statistically significant comparisons between the groups at 15 to 23 weeks' gestation. Fetuses with Down syndrome displayed no statistically significant differences in the cephalic index or the biparietal diameter compared with controls at a given gestational age. Significant femur length shortening was observed, but the greatest statistical difference was noted for the biparietal diameter/femur length ratio. This ratio was found to decrease with gestational age in the normal population and was consistently elevated in the Down syndrome population (compared with control) throughout the second trimester. With a cutoff value of 1.5 SD above the normal population mean for the biparietal diameter/femur length ratio, 50% to 70% of fetuses with Down syndrome could be identified in 6% of the total population ($p < 0.0001$). This preliminary study suggests that the biparietal diameter/femur length ratio may prove superior to current Down syndrome screening methods and, as a third independent variable, may significantly enhance the sensitivity and specificity of combined maternal age/maternal serum α-fetoprotein screening modalities. (AM J OBSTET GYNECOL 1987;157:803-8.)

Key words: Down syndrome, sonography, biparietal diameter, femur length, screening methods

The antenatal detection of Down syndrome before 24 weeks' gestation remains a major epidemiologic challenge. The sensitivity of maternal age–based Down syndrome screening programs has decreased as a result of a progressive decline in births to women over 34 years of age. Presently, <20% of Down syndrome cases are associated with a maternal age >34 years.[1] The introduction of screening techniques for Down syndrome that use decreased maternal serum α-fetoprotein concentrations enables assessment of the 95% of pregnant women <35 years old who are responsible for 80% of Down syndrome fetuses. However, such programs are also associated with a low sensitivity (13% to 21%) and high false-positive rate (7% to 9%).[2, 3]

The increasing use of routine ultrasound in the second trimester has stimulated an interest in discovering a simple, readily reproducible sonographic method that identifies pregnancies at high risk for Down syndrome. Thus we performed a retrospective analysis of sonographically derived biometric differences between Down syndrome and normal fetuses at two prenatal diagnosis centers. A screening method exploiting the increased biparietal diameter/femur length ratio of Down syndrome fetuses is proposed.

Material and methods

Control population. The ultrasound reports of all consecutive patients undergoing genetic amniocentesis at the Yale University Perinatal Unit who were between 15 and 23 weeks' gestation were reviewed for the period January 1, 1986, to October 1, 1986. Indications for amniocentesis included advanced maternal age (63%), abnormal maternal serum α-fetoprotein concentrations (34%), and a family history of genetic disorders (3%). Exclusion criteria included a discrepancy of >1.5 weeks between the menstrual age and gestational age derived from biparietal diameter and femur length measurements,[4, 5] the failure to record both biparietal diameter and femur length measurements, or the presence of anatomic or chromosomal anomalies. A total of 349 patients was available for analysis in the New Haven control population.

Utilizing similar exclusion criteria, the ultrasound reports of 195 consecutive patients undergoing genetic amniocentesis for advanced maternal age and low ma-

ternal serum α-fetoprotein concentration at the Diagnostic Ultrasound Associates in Boston were reviewed for the period August 1, 1986 to October 1, 1986. Gestational ages ranged from 15 to 21 weeks.

Down syndrome population. All consecutive karyotypic diagnoses of trisomy 21 made at the Yale University Cytogenetics Laboratory from January 1, 1984, through October 1, 1986, were ascertained. Karyotype sources included amniotic fluid derived from genetic amniocenteses (91%) and lymphocytes from neonates with Down syndrome stigmatas (9%). Those women bearing Down syndrome fetuses who had undergone second-trimester obstetric ultrasound examinations at the Yale Perinatal Unit before the diagnosis of Down syndrome were identified. Exclusion criteria consisted of intrauterine fetal death, hydrocephalus, inaccurate dating criteria, or a failure to record both biparietal diameter and femur length measurements. Ultrasound data were available in 35 patients from 15 to 23 weeks' gestation.

Consecutive karyotype diagnoses of trisomy 21 made after genetic amniocenteses at the Diagnostic Ultrasound Associates were identified for the period January 1, 1985, through October 1, 1986. Exclusion criteria were similar. Data were available from 20 patients with Down syndrome fetuses from 15 to 19 weeks' gestation.

Ultrasound techniques and equipment. The biparietal diameter was measured with electronic calipers from leading edge to leading edge at the level of the thalami. The femur was preferentially visualized from the greater trochanter to the end of the ossified shaft, perpendicular to the long axis of the bone, and its length was recorded with electronic calipers. The cephalic index was calculated by dividing the biparietal diameter by the occipitofrontal diameter measured at the same level.

The ultrasound equipment used in New Haven included the General Electric models RT 2600 and 3000 (3.5 and 5.0 mHz linear array transducers; Rancho Cardova, California), the Advanced Technology Laboratories Ultramark 4 (3.5 and 5.0 mHz linear array transducers; Botnell, Washington), and the Acuson 128 (3.0 mHz linear array transducer). The equipment used in Boston included an Acuson 128 or ATL 300 (3.0 and 3.5 mHz sector transducers). To ensure an accurate estimate of the femur length measurements with the sector scanner, the femur lengths were repeatedly imaged and the longest possible length was recorded.

Data collection and statistical analysis. Ultrasound

reports were reviewed and the indications for evaluation, gestational age, biparietal diameter, femur length, and cephalic index were recorded. The calculation of the cephalic index was not available for the Boston population. Hadlock's formula[6] and Jeanty's formula[7] were used in the estimation of gestational age based on biparietal diameter and femur length, respectively.

The biparietal diameter, femur length, biparietal diameter/femur length ratio, and cephalic index were compared in the Down syndrome and control populations at given gestational ages. Differences between cases and controls were identified by Student's *t* test and a Wilcoxon signed rank test. The ability of specific biparietal diameter/femur length cutoff values to discriminate between Down syndrome and normal fetuses was assessed by χ^2 analysis and Fisher's exact test. The effect of gestational age on the biparietal diameter/femur length ratio was assessed by general linear model regression analysis.

Results

There was a consistent underestimation of the femur length for a given gestational age in the New Haven population, and a consistent overestimation in the Boston population when compared with Jeanty's nomogram.[7] The differences between the two centers were statistically significant ($p < 0.0001$) from 16 to 19 weeks' gestation, and precluded combining the two centers' data sets.

New Haven results. Power analysis[4] demonstrated that adequate numbers of cases and controls were available to allow for statistically meaningful (>80%) comparisons from 16 to 17, 17.5 to 18.5, and 20 to 21 weeks' gestation (Table I). Other gestational week intervals contained insufficient cases. No statistically significant differences were detected between cases and controls for mean gestational age, suggesting similar gestational age distributions within the chosen intervals. No statistically significant differences were noted for cephalic index or biparietal diameter. There was, however, a statistically significant shortening of femur lengths in the Down syndrome fetuses in each gestational week interval. Furthermore, the biparietal diameter/femur length ratio resulted in the highest statistically significant differences between the two populations. A Wilcoxon signed rank test confirmed the statistically significant differences for femur length and particularly for the biparietal diameter/femur length ratio (Table I).

Boston results. Identical findings were noted for the Boston center (Table II). Gestational age intervals were again chosen to maximize power (>80%) and included 15.0 to 16.0 and 16.5 to 17.5 weeks' gestation. No significant differences were noted for gestational age or biparietal diameter between the case and control groups. Statistically significant differences were noted for femur length and particularly the biparietal diameter/femur length ratio between the two groups.

Variation in biparietal diameter/femur length ratios across gestational age. The biparietal diameter/femur length ratio (BPD/DL) was noted to decrease across gestational age (GA) in both centers' control populations according to the following formulas:

$$BPD/FL = 3.222 - 0.125\ (GA) + 0.002\ (GA)^2$$
$$BPD/FL = 2.406 - 0.052\ (GA)$$
$$(R^2 = 0.56;\ p < 0.0001;\ \text{New Haven})$$
$$(R^2 = 0.36;\ p < 0.0001;\ \text{Boston})$$

The biparietal diameter/femur length ratio was consistently higher in the Down syndrome population at

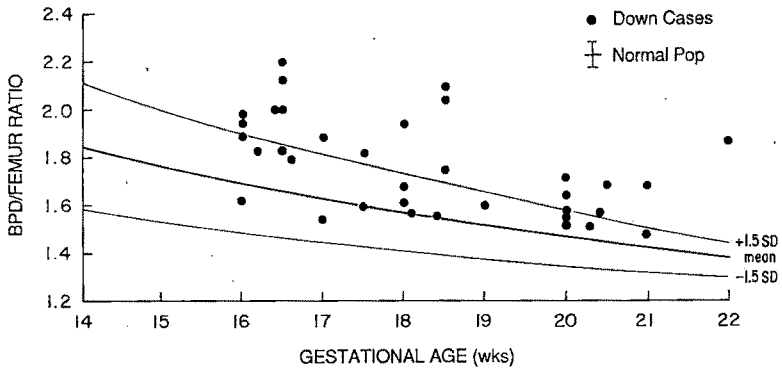

Fig. 1. The biparietal diameter/femur length ratio *(BPD/FEMUR)* in the normal population (±1.5 SD) and in Down syndrome cases for the New Haven population.

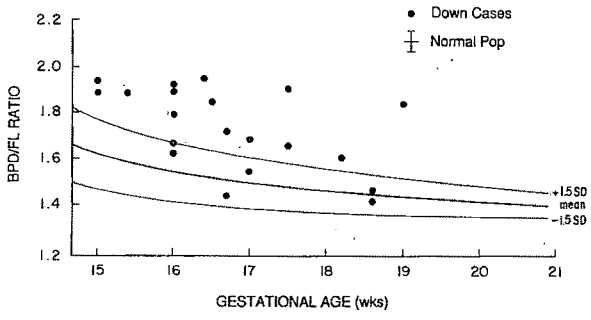

Fig. 2. The biparietal diameter/femur length ratio *(BPD/FL)* in the normal population (±1.5 SD) and in Down syndrome cases for the Boston population.

all gestational ages. For the New Haven population, 51% of Down syndrome cases were found to have a biparietal diameter/femur length ratio 1.5 SD above the control population mean for a given gestational age, while only 6% of Down syndrome fetuses were below the mean (Fig. 1). For the Boston population, 70% of Down syndrome fetuses were 1.5 SD above the control population mean, while only 10% were at or below the mean (Fig. 2).

Predictive value of biparietal diameter/femur length ratio in discriminating between Down syndrome and normal fetuses. The sensitivity and false positive rate of the biparietal diameter/femur length ratio in differentiating Down syndrome from normal fetuses were also evaluated for each center (Table III). With a cutoff value of 1.5 SD above the mean ratio for the normal New Haven population, 51% of Down syndrome fetuses were identified with a false positive rate of 7%. Given a general population incidence for Down syndrome at term of 1/1000[6] and a fetal loss rate of 29%,[5] the incidence of Down syndrome in the second trimester should be 1/710 and the resulting positive predictive value of the proposed biparietal diameter/femur length ratio cutoff would be 1/103. Thus 102 amniocenteses on non–Down syndrome gestations would be necessary for each Down syndrome diagnosis. In a high-incidence population, such as women 35 years old, the anticipated incidence of Down syndrome at the time of genetic amniocentesis would be 1/270,[8] and thus 37 amniocenteses would be required for one diagnosis of Down syndrome (positive predictive value 1/37).

For the Boston center, a cutoff value of 1.5 SD above the mean ratio for the control population would identify 70% of cases with a false-positive rate of 4.6%. The positive predictive value for the general obstetric population would be 1/47 and that for women at age 35 years would be 1/18.

The ability of the femur length measurement alone to differentiate Down syndrome from normal fetuses was also assessed. With a cutoff value of 1.5 SD below the control (New Haven) population mean, 40% of Down syndrome fetuses were identified, while for the Boston center 60% of Down syndrome fetuses were identified. Femur length, therefore, proved less accurate than the biparietal diameter/femur length ratio in discriminating Down syndrome fetuses.

Comment

Recently, characteristic sonographic "signs" for the Down syndrome fetus have been proposed as adjuncts to screening programs. The sonographic finding of posterior occipital-nuchal skin thickening may be present in up to 45% of Down syndrome fetuses in the second trimester.[9] The practical application of this observation remains to be determined. In addition, duodenal obstruction occurs in 8% of Down syndrome infants[10] and has been proposed as a marker for the condition.[11] Unfortunately, the literature suggests that the diagnosis of duodenal obstruction can rarely be made before 24 weeks' gestation.[12] Ventricular septal and atrioventricular canal defects are present in up to 50% of Down syndrome infants,[13] but it is not clear

Table III. Sensitivity and false-positive rate of the biparietal diameter/femur length ratio in the detection of Down syndrome

what percentage of these defects can be identified with an ultrasound screening examination. The use of standard ultrasound biometry to differentiate Down syndrome from normal fetuses has great appeal. Both biparietal diameter and femur length are readily and accurately measured during a basic ultrasound examination. These measurements require neither sophisticated training nor expensive ultrasound equipment.

Initial efforts to define a biometric marker of Down syndrome used the long-standing observation that Down syndrome infants tend toward brachycephaly (increased cephalic index).[14] Perry et al.,[15] however, were not able to differentiate normal from Down syndrome fetuses on the basis of an increased cephalic index during second-trimester sonography. Our data confirm their observation, with no difference in cephalic index noted between case and control populations (Table I). In addition, we have observed that while femur lengths were significantly shorter in Down syndrome fetuses, consistent with their shorter stature,[16] femur length per se was not the optimal discriminator. By combining biparietal diameter and femur length measurements into a ratio, discrimination between Down syndrome and normal fetuses is enhanced. This finding is in agreement with the observations of Collett et al.,[17] who noted that the biparietal diameter/femur length ratio was elevated in fetal Down syndrome. This suggests that in the normal population, shorter femur lengths are associated with smaller biparietal diameters, perhaps as a consequence of inaccurate dating or symmetric growth retardation. Because the biparietal diameter/femur length ratio is far less affected by changes in gestational age than is femur length alone, it should provide a more reliable clinical marker for Down syndrome.

The use of the biparietal diameter/femur length ratio with a 1.5 SD cutoff, between 15 and 23 weeks' gestation, allows for the detection of Down syndrome in the general obstetric population with a sensitivity of 50% to 70%, greater than that of either low maternal serum α-fetoprotein concentration (≤0.5 multiple of the median) or maternal age–based (>34 years) screening programs alone (<20% each). In addition, the positive predictive value exceeds that of maternal age–based screening; thus a far larger number of Down syndrome fetuses are identified with fewer unnecessary amniocenteses.

A number of potential limitations are present in this study. The Down syndrome sample size is small. However, a power analysis suggests >90% probability of identifying a true difference between the Down syndrome and control populations.[18] An additional source of error may result from the tendency for sonographers to minimize gestational age discrepancies between biparietal diameter and femur length measurements. This phenomenon could cause a significant reduction in the ratio's sensitivity for the detection of Down syndrome, because the greater the biparietal diameter/femur length discrepancy, the greater the likelihood of remeasurement.

The difference in femur length measurements between the two centers probably reflects differences in methodology and not variations in population. The use of a sector transducer results in a relative overestimation of long bone length, in a plane perpendicular to the bone's long axis, when compared with the linear array transducer.[19] Furthermore, while the greater trochanter provides a ready landmark for measurement, sonographers may vary in their assessment of the distal termination of the femoral diaphysis. We postulate that an overestimation of femur length accounts for the Boston center's greater diagnostic sensitivity. The smaller biparietal diameter/femur length ratio in the Boston control population may paradoxically amplify

the effect of femur length shortening in the Down syndrome population. It is therefore crucial that each center establish its own biparietal diameter/femur length limits of confidence in the second trimester for Down syndrome risk assessment.

The role of the biparietal diameter/femur length ratio in prenatal screening for Down syndrome remains to be confirmed by further investigations. Variation in ultrasound equipment and technique may lead to significant effects on a given center's diagnostic efficacy. Nonetheless, this method appears at least comparable to methods that use maternal serum α-fetoprotein and/or maternal age. Since Baumgarten et al.[20] have demonstrated that ascertainment of Down syndrome risk by a combination of maternal serum α-fetoprotein level and maternal age may improve diagnostic accuracy, the addition of a third independent predictor (biparietal diameter/femur length ratio) of Down syndrome risk could further enhance this diagnostic accuracy. The effect of the biparietal diameter/femur length ratio on the relative risk of Down syndrome could be assessed and used to provide a patient with an adjusted risk based on all three parameters.

We thank Ms. Barbara Coster for her assistance in the preparation of this article.

Colposcopic correlates of cervical papillomavirus infection

Michele M. Follen, M.D., Richard U. Levine, M.D., Ellen Carillo, R.N., Ralph M. Richart, M.D., Gerard Nuovo, M.D., and Christopher P. Crum, M.D.*

New York, New York

We compared the colposcopic and histologic features of 39 papillomavirus-related cervical lesions with their associated human papillomavirus type. Two thirds of the lesions contained human papillomavirus type 16–related deoxyribonucleic acid, and 69% of them were classified as cervical intraepithelial neoplasia I or II, in contrast to 92% of lesions containing human papillomavirus 6/11 deoxyribonucleic acid. On histologic examination, low-grade cervical intraepithelial neoplastic lesions tended to be sharply demarcated and have an uneven or granular surface contour. In contrast, high-grade lesions often had diffuse borders and were usually smooth in appearance. Both low- and high-grade lesions displayed variable degrees of whiteness, thickness, and papillomatous configurations. Patterns of coarse punctation were more common in higher grade cervical intraepithelial neoplastic lesions and in those containing human papillomavirus 16. Predictably, the colposcopic features of lesions containing human papillomavirus 6/11 deoxyribonucleic acid sequences compared closely with those of low-grade cervical intraepithelial neoplasia. In contrast, human papillomavirus 16–associated cervical intraepithelial neoplasia exhibited a greater spectrum of colposcopic patterns, including those associated with condyloma and low- and high-grade cervical intraepithelial neoplastic lesions. We conclude that, although a portion of low- and high-grade cervical intraepithelial neoplastic lesions can be distinguished colposcopically, a significant number of lesions containing features of low-grade cervical intraepithelial neoplasia or condyloma contain human papillomavirus 16 deoxyribonucleic acid and cannot be distinguished from presumably innocuous human papillomavirus infections. (Am J Obstet Gynecol 1987;157:809-14.)

Key words: Colposcopy, papillomaviruses, cervical intraepithelial neoplasia

In the past 10 years colposcopy has become an accepted and to most gynecologists necessary screening tool for evaluating women with abnormal Papanicolaou smears. With colposcopy it is possible to visualize directly precancerous lesions of the cervix and lower genital tract, to determine their distribution and extent, and to select the most appropriate areas for biopsy to ensure an accurate diagnosis. With this approach, it is possible to rule out cancer in a large proportion of cases, facilitating conservative ablation with cryotherapy or laser in most.[1-3]

The possibility that colposcopy may predict histologic changes has been suggested by some authors, who have equated increases in vascular atypia with increasing grade of cervical intraepithelial neoplasia or dysplasia.[1] With the discovery that papillomaviruses are associated with precancerous lesions of the cervix, attention has focused on distinguishing infections associated with presumably benign and potentially precancerous lesions. Reid et al.[3] introduced a comprehensive battery of colposcopic indices that they claimed would differentiate a large proportion of condylomatous or low-grade cervical intraepithelial neoplastic lesions from high-grade lesions or carcinoma in situ.[3] However, Barasso et al.[4] were unable to formulate reliable colposcopic criteria for this distinction.

The observation that certain papillomaviral deoxyribonucleic acid (DNA) strains are preferentially associated with cancer has prompted efforts to distinguish precancerous lesions associated with these strains. Human papillomavirus types 16, 18, 31, 35, and others have been associated with cancers and a spectrum of cervical intraepithelial neoplastic lesions, as opposed to human papillomaviruses 6 and 11 (and others), which are associated with condylomas.[5-12] However, low-grade cervical intraepithelial neoplastic lesions and condylomas contain many common features and may be difficult to distinguish on colposcopic examination. Accordingly, it is uncertain whether colposcopy is sufficiently sensitive to distinguish cervical lesions associated with different human papillomavirus types.[3, 4, 11, 12]

Our purpose was to determine if a battery of colposcopic indices would distinguish between infections

Fig. 1. This cervical intraepithelial neoplasia 1/condyloma lesion is sharply demarcated and contains two growth patterns, including mosaiform *(lower right)* and papillomatous areas *(center and bottom left)*. DNA from this lesion contained sequences closely related to human papillomavirus 6/11 DNA.

Fig. 3. This cervical intraepithelial neoplasia 1/condyloma lesion is poorly demarcated anteriorly, with snow-white epithelium from the 6 to 9 o'clock positions. The human papillomavirus DNA from this lesion was closely related to human papillomavirus 6/11.

Fig. 2. This cervical intraepithelial neoplasia 2 lesion is sharply demarcated, with a prominent mosaiform pattern similar to that in Fig. 1. DNA from this lesion contained sequences closely related to human papillomavirus 16.

associated with human papillomavirus type 16 and those associated with types 6 and 11, the latter commonly found in condylomas of the lower genital tract. We present evidence that infections associated with different human papillomavirus types exhibit a wide array of colposcopic abnormalities and that their distinction is not always possible. Our inability to separate these processes may relate to a number of factors, including the morphologic similarities between all papillomavirus infections.

Material and methods

Selection of case material. All patients selected were private patients referred to one of the coauthors (R. U. L.) for the evaluation of an abnormal Papanicolaou smear. All patients underwent colposcopy, colpophotography, and colposcopically directed biopsies. Patients were included in this study if the colposcopy, photographic slide, and biopsy results were satisfactory and if analysis of their biopsy samples disclosed the presence of a papillomaviral DNA. The DNA hybridizations were performed in close collaboration with Dr. Saul Silverstein at the Cancer Research Center, Columbia University College of Physicians and Surgeons.

Colposcopic classification. Colposcopic classification of the cervical lesions was based on review of the slides

Fig. 4. This cervical intraepithelial neoplasia 1/condyloma lesion contains multiple areas of well demarcated thick white epithelium with prominent coarse punctation. The human papillomavirus DNA from this lesion was of undetermined type.

Fig. 5. This cervical intraepithelial neoplasia 3 lesion is poorly demarcated, with thin, gray-white epithelium from the 1 to 3 o'clock positions. The human papillomavirus DNA isolated from this lesion was closely related to human papillomavirus 16.

only. Three of us (M. F., R. U. L., and C. P. C.) reviewed the slides and classified the abnormalities according to a modification of the indices previously proposed.[3] These included degree of whiteness, demarcation, thickness, certain features of surface contour, and vascular changes. Vascular changes were characterized as absent, mosaiform or horizontal, fine punctation or vertical (including warty), true mosaic, coarse punctation, and atypical vessels (Figs. 1 to 6). Coarse punctation consisted of larger caliber vessels with irregular intercapillary distances. The colposcopic findings were then correlated with both the histologic diagnosis and the human papillomavirus DNA type detected in the tissue.

Histologic classification. All biopsy specimens were reviewed by two of us (C. P. C. and R. M. R.) and classified as negative (i.e., epidermidization, squamous metaplasia, or parakeratosis), or cervical intraepithelial neoplastic lesion type 1, 2, or 3. For the purposes of this study, the distinction between low-grade cervical intraepithelial neoplasia and flat condyloma was not made, becuase they share similar morphologic features and may at times be difficult to distinguish from one another.[12]

Analysis for human papillomavirus DNA. One half of each biopsy sample was frozen, examined by frozen section, then analyzed by Southern blot hybridization for the presence of human papillomavirus DNA sequences as described previously.[10] With a series of low stringent hybridizations with types 6 and 11, 16, and 18, tissue DNA samples were screened for the presence of human papillomavirus DNA sequences followed by exposure of hybridized filters to x-ray film. After exposure, the filters were washed under stringent conditions, reexposed, and the hybridization signals were compared. If signals remained strong under both conditions, the human papillomavirus DNA was designated as closely related to the probe used. If the signal significantly diminished after the stringent wash, the virus was assumed to be different from the probe(s) used. The human papillomavirus DNA samples were thus designated as one of the following: type 6 or 11, type 16, type 18, a mixture of more than one type, and a type other than 6, 11, 16, and 18.

Results

Patient population. Forty-four patients were included in the study. They ranged in age from 20 to 58 years (mean 33 years). All were referred because of an abnormal Papanicolaou smear. After biopsy and treatment, the patients were followed up to 36 months (mean 10 months).

Histopathology. Smears were taken at the time of

Fig. 6. This lesion contains a "true mosaic" vascular pattern, characterized by thick white epithelium and an interlacing network of prominent vessels accompanied by punctation. This was a cervical intraepithelial neoplasia type 3 lesion with gland involvement. Viral studies were not performed in this case.

colposcopy and biopsy from 34 patients. They included three normal, 13 with atypia suggesting grade 1 cervical intraepithelial neoplasia or condyloma, 18 with grade 1 cervical intraepithelial neoplasia, five with grade 2 cervical intraepithelial neoplasia, and five with grade 3 cervical intraepithelial neoplasia. Biopsy information was available from all patients. Twenty-two were diagnosed as having grade 1 cervical intraepithelial neoplasia or condyloma, 13 as having grade 2 lesions, and nine as having grade 3 lesions (Table I).

DNA hybridization. The viral DNA types detected are shown in Table I. Thirteen lesions contained sequences closely related to human papillomaviruses 6 or 11, 26 were closely related to type 16, two lesions contained a mixture of types, including 6/11 and 16, and two lesions contained types not closely related to the probes used.

Correlation of lesion grade with colposcopic index. Most of the lesions, including all grades, were gray-white in color (Table II). Most grade 1 cervical intraepithelial neoplasia lesions were sharply demarcated, whereas most grade 3 lesions had diffuse borders. Equal proportions of lesions were thick and thin, except for grade 3 lesions, most of which were thin. Most

Table I. Diagnosis versus human papillomavirus DNA type

	Cervical intraepithelial neuroplasia			
Viral DNA type	*Grade 1**	*Grade 2*	*Grade 3*	*Total*
16	8	10	8	26
6/11	10	2	1	13
16/11	1	1	—	2
Not determined†	3	—	—	3
	22	13	9	44

*For these purposes flat condyloma and grade cervical intraepithelial neuroplasia with koilocytotic atypia were classified under grade 1 cervical intraepithelial neuroplasia.

†Human papillomavirus type other than types 6, 11, or 16.

grade 1 lesions had an uneven or granular surface contour, in contrast to type 3 lesions, which tended to be smooth. Both grades 1 and 2 lesions contained papillomatous features. Certain vascular changes, including primarily mosaiform or no abnormal vascular pattern, were evenly distributed among all three grades. In contrast, coarse punctation was seen in 19% of higher grade cervical intraepithelial neoplasia versus 6% of low-grade cervical intraepithelial neoplasia/condyloma.

Correlation of viral DNA strain with colposcopic index. Most of the lesions containing human papillomavirus 16 DNA sequences were gray-white, while lesions containing type 6/11 sequences were nearly equally divided between gray-white and snow white (Table II). Although human papillomavirus 16–associated lesions were nearly equally divided between sharp and diffuse, most 6/11–associated lesions were sharply defined. The majority of all lesions were thin, with a rough or uneven surface contour. Interestingly, the majority of type 16–associated lesions did not display marked vascular atypia, because the majority of all lesions contained either a mosaiform vascular pattern or no significant vascular changes. Predictably, a greater percentage of lesions containing type 16 (16%) contained coarse punctation, in contrast to those containing type 6/11 (8%). A single human papillomavirus type 16–containing lesion with true vascular atypia was a grade 3 cervical intraepithelial neoplasia lesion that also contained invasive carcinoma.

Comment

Our goal was to determine if cervical lesions associated with specific human papillomavirus DNA strains could be predicted from colposcopic examinations. There is evidence that both the grade of a lesion and its associated viral type may influence the risk of progression to cancer if the lesion is not treated. Colposcopy, as designed, is part of a diagnostic protocol and, irrespective of the results of this or any other study, we would not recommend that it be used alone to decide

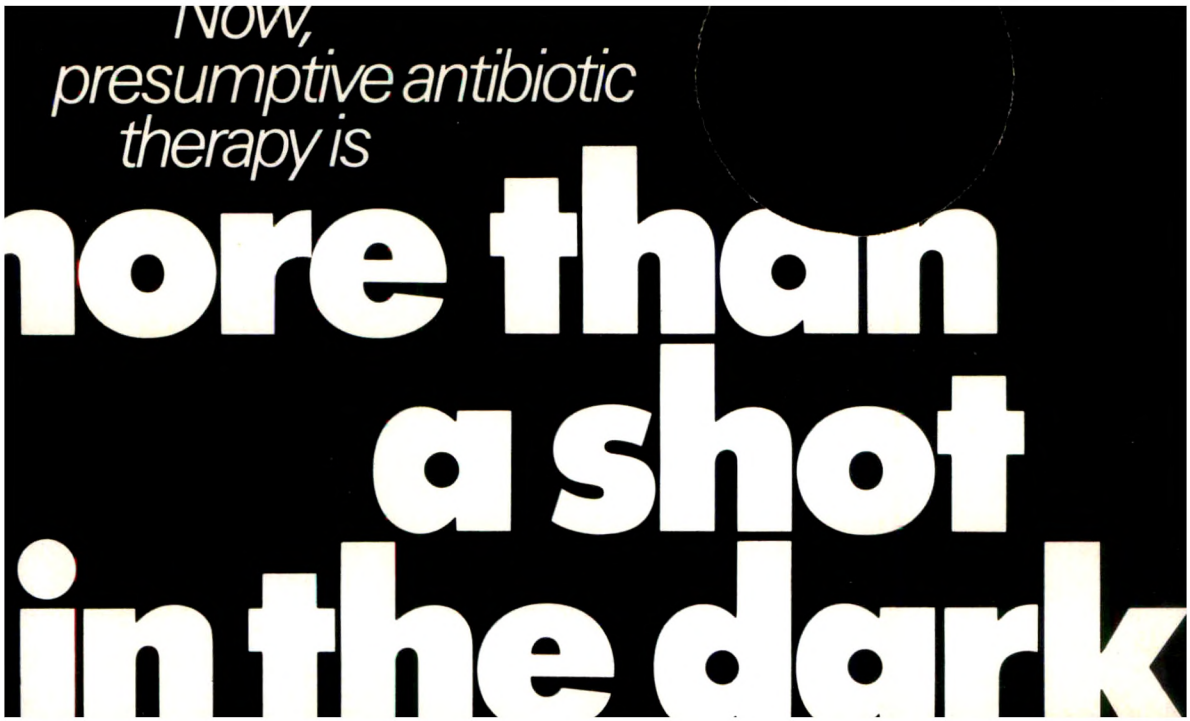
if a cervical lesion was high or low risk, or if it should be removed. Nevertheless, in view of the close association between histology, viral DNA type, and biologic behavior, understanding the relationship of colposcopic presentation to histologic and viral parameters is important.[5-12]

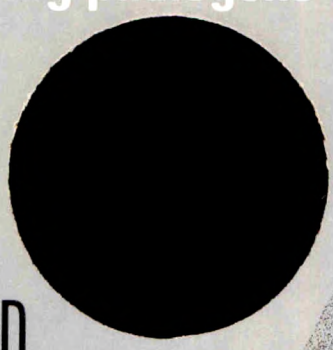
As shown by the correlations in Table II, we were not able to establish a strong relationship between the colposcopic parameters outlined and lesion grade. This lack of a precise correlation parallels a recent study by Barasso et al.,[4] who found that many cervical intraepithelial neoplastic lesions shared the colposcopic features of condyloma. They found that three parameters associated with condyloma—irregular staining with Lugol's stain, the presence of asperites, and satellite lesions—were found in over two thirds of lesions with the histologic features of cervical intraepithelial neoplasia. This is in contrast to Reid et al.[3] who found that colposcopic indices could usually distinguish between lesions at the low (condyloma and grade 1 cervical intraepithelial neoplasia) and high (grade 3 cervical intraepithelial neoplasia) end of the spectrum. Although we were not able to confirm the latter findings, it is important to stress that our study consisted of lesions presenting primarily with low-grade Papanicolaou smears (grade 1 cervical intraepithelial neoplasia or condyloma) and lesions on the lower end of the cervical intraepithelial neoplasia spectrum. Moreover, most did not display prominent vascular changes on colposcopic examination. The vascular changes seen in this population consisted primarily of horizontal capillary arcades (mosaiform), which we and others have distinguished from the more classical mosaic traditionally associated with higher grade precancerous lesions[1, 3] (Figs. 1, 2, and 6). As would be expected, coarse punctation was more commonly observed in higher-grade lesions and in those containing human papillomavirus 16. However, most lesions were in the lower end of the cervical intraepithelial neoplasia spectrum, and this feature was not prevalent enough to serve as a good discriminator of lesion grade. Thus, because there were few high-grade lesions in our study for comparison, it would be premature to state that most low-grade lesions cannot be distinguished from high-grade cervical intraepithelial neoplasia.

The important finding in our study is the presence of human papillomavirus type 16 DNA in both low- and high-grade cervical intraepithelial neoplasia and in lesions displaying a wide spectrum of colposcopic features. Human papillomavirus 16 has been associated with high-grade precancerous lesions (cervical intraepithelial neoplasia grade 3) and invasive cancers.[6] We and others have found that human papillomavirus 16 DNA is the human papillomavirus DNA that is most commonly isolated from cervical lesions, including many lesions that exhibit features of both condyloma and cervical intraepithelial neoplasia.[9-12] This would explain the association of type 16 with many lesions classified as grade 1 cervical intraepithelial neoplasia in our study, as well as the close correlation between type 16 and lesions with colposcopic features associated with low-grade cervical intraepithelial neoplasia or condyloma.



The fact that human papillomavirus 16 DNA is found in a wider spectrum of cervical intraepithelial neoplastic lesions than type 6/11 may explain some of the col-

poscopic findings. For example, most low-grade cervical intraepithelial neoplastic lesions (including condylomas) were sharply demarcated, whereas high-grade lesions tended to have diffuse borders. Accordingly, lesions containing type 6/11 were usually sharply demarcated, in keeping with the association of type 6/11 with low-grade cervical intraepithelial neoplasia or condyloma. However, type 16–related lesions were equally sharp and diffuse in appearance, reflecting the association of type 16 with a broader spectrum of colposcopic abnormalities, including both low- and high-grade cervical intraepithelial neoplasia. As mentioned, coarse punctation, while more common in human papillomavirus type 16—containing lesions, was infrequently present in all lesions, many of which contained type 16.



The morphologic overlap between low-grade cervical intraepithelial neoplasia and condyloma and the association of human papillomavirus 16 DNA with lesions throughout the cervical intraepithelial neoplasia spectrum emphasizes the difficulty of distinguishing all potential cancer precursors at the colposcopic level. This problem of recognition is further compounded by the possibility of clinically and histologically latent human papillomaviral infection, the natural history of which is still unknown.[13, 14] This would place the value of colposcopy primarily at detecting lesions and distinguishing their limits and any areas within the lesion containing abnormal vessels that might represent invasive cancer. Given that potentially oncogenic human papillomavirus DNA strains are found in all grades of precancers (including normal-appearing mucosa), colposcopy is not an appropriate method by itself for predicting the natural history of a cervical lesion.

TRODUCES

GETED

IOTIC POWER

argets clinically important aerobes and anaerobes†

New UNASYN® (ampicillin sodium/sulbactam sodium) offers a new level of confidence in coverage of the pathogens of concern in mixed infections.

argeted for success in treatment

New UNASYN is highly effective in gynecologic, intra-abdominal, and skin and skin-structure infections.*

argeted to inhibit β-lactamase, the primary source of acterial resistance[1]

New UNASYN irreversibly inactivates a broad range of β-lactamases responsible for resistance.[2] And UNASYN does not promote the emergence of resistant strains.[3]

etains penicillin-class safety and toleration

New UNASYN provides outstanding safety documented in worldwide clinical use.[4] As with all penicillins, UNASYN is contraindicated in individuals who have a history of hypersensitivity reactions to any of the penicillins.

NEW **Unasyn®** IM IV

(ampicillin sodium/sulbactam sodium)

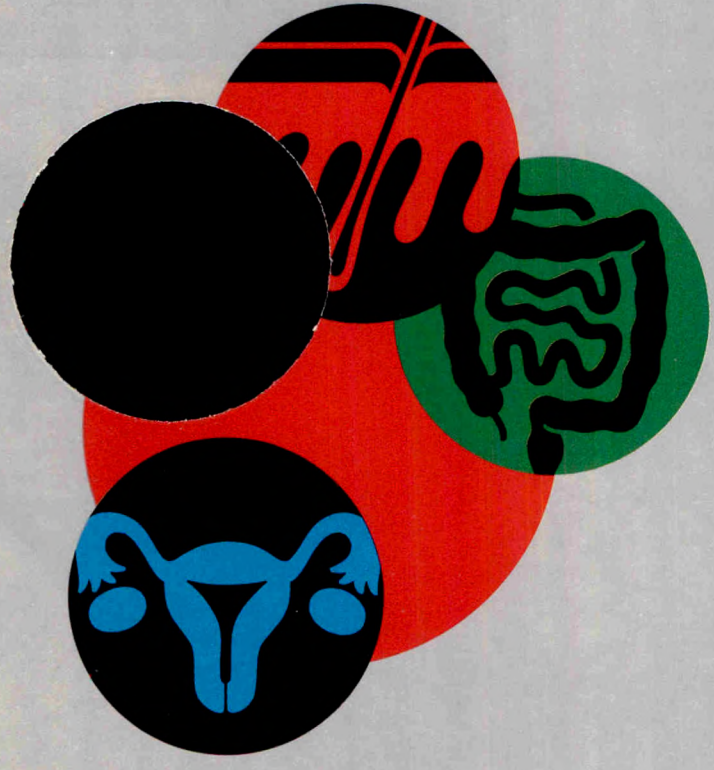
On target in mixed infection*

*Due to susceptible strains of indicated organisms.

†In vitro susceptibility does not necessarily imply a correlation with in vivo results.

TARGETED

Uniformly high clinical response rates in mixed aerobic/anaerobic infections*



In an extensive multicenter study, new UNASYN® (ampicillin sodium/sulbactam sodium) proved highly effective in gynecologic, intra-abdominal, and skin and skin-structure infections: Satisfactory response with UNASYN ranged from 90.9% to 98.3%.[4] Results were comparably high in the subset of patients infected with ampicillin-resistant pathogens: 89.0% to 97.1%.[4]

Satisfactory clinical response was defined as cure or marked-to-moderate improvement. Bacteriologic eradication included complete eradication, eradication with superinfection, and eradication with reinfection.

Gynecologic infection
...such as pelvic inflammatory disease and endometritis.

Intra-abdominal infections[*4] ...such as peritonitis, appendicitis, and abscesses.

Skin and skin-structu infections[*4] ...such as deep skin infections, perirectal absces and decubitus ulcers.

Please see brief summary of UNASYN® (ampicillin sodium/sulbactam sodium) prescribing information on last page of this advertisement.

R SUCCESS

Multicenter study results[4]	Overall		Resistant group[†]
Clinical efficacy	**91.1%** (123/135 patients)	satisfactory response	**94.1%** (48/51 patients)
Bacteriologic efficacy	**96.1%** (422/439 isolates)	eradicated	**95.2%** (80/84 isolates)
Clinical efficacy	**90.9%** (180/198 patients)	satisfactory response	**89.0%** (129/145 patients)
Bacteriologic efficacy	**93.3%** (528/566 isolates)	eradicated	**90.2%** (248/275 isolates)
Clinical efficacy	**98.3%** (231/235 patients)	satisfactory response	**97.1%** (136/140 patients)
Bacteriologic efficacy	**92.8%** (517/557 isolates)	eradicated	**92.0%** (184/200 isolates)

[†]Infections included ampicillin-resistant organisms.

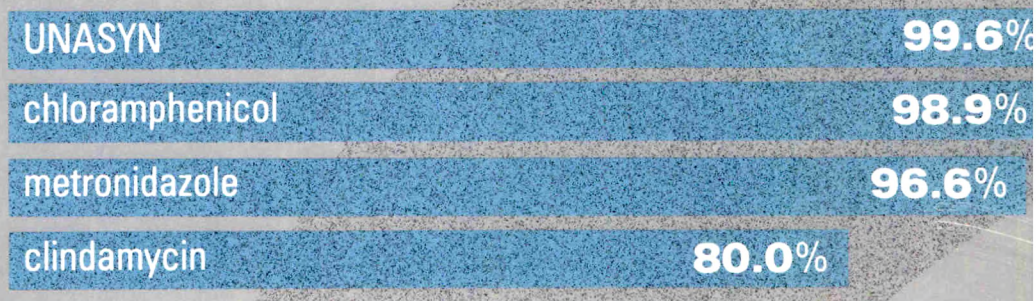
NEW FROM ROERIG

Unasyn® IM IV

(ampicillin sodium/sulbactam sodium)

On target in mixed infection*

*Due to susceptible strains of indicated organisms



TARGETED FO

Highly active in vitro* against the important pathogens of mixed infections†

ANAEROBES

"The activity [of UNASYN® (ampicillin sodium/sulbactam sodium)] against all strains tested [272 anaerobes] was higher than that of any other drug tested; 99.6% were inhibited by [UNASYN at breakpoint]...."[5]

Percent of anaerobes susceptible at breakpoint‡§[5]

UNASYN is three times more active than cefoxitin and at least four times more active than moxalactam against *Bacteroides fragilis* (N = 71).[6]

AEROBES

New UNASYN provides a comprehensive gram-positive spectrum, with powerful activity against virtually all aerobic cocci, including:

- ***Staphylococcus aureus*** (β-lactamase + and −)
- ***S. epidermidis*** (β-lactamase + and −)
- ***S. saprophyticus*** (β-lactamase + and −)
- **Enterococci**‖
- ***Streptococcus pneumoniae***‖
- ***S. pyogenes***‖
- ***S. viridans***‖

UNASYN also possesses a practical spectrum of gram-negative activity,* which includes pathogens frequently encountered in mixed infections,† such as *Escherichia coli* and *Proteus mirabilis.*

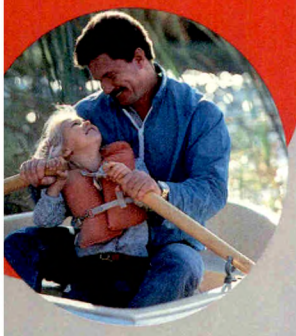
Reliable penicillin-class safety profile

In worldwide clinical trials with 2,258 patients, less than 1% discontinued treatment with UNASYN due to adverse experiences.[4] The most frequently reported adverse reactions were pain at injection site, 3.2%; diarrhea, 3%; and rash, <2%.[4]

As with all penicillins, UNASYN is contraindicated in individuals who have a history of hypersensitivity reactions to any of the penicillins.

YOUR NEEDS

Destroys bacterial resistance through inhibition of β-lactamase



In new UNASYN, the β-lactamase inhibitor sulbactam inactivates a broad range of enzymes responsible for bacterial resistance.[2]

Unlike clavulanic acid and cefoxitin, sulbactam is a negligible inducer of Type I chromosomal β-lactamases[7,8]; the risk of spontaneous emergence of resistance during therapy is therefore reduced, as is the possibility of antagonism with ampicillin.[7,9]

In addition, even with multiple exposures to sublethal concentrations, UNASYN did not promote the emergence of resistance in β-lactamase-producing organisms.[3] Cephalosporin controls—cephalexin and cefaclor—exhibited significant increases in MIC values (>100 μg/mL) by the fourth exposure.[3]

*In vitro susceptibility does not necessarily imply a correlation with in vivo results.
†Due to susceptible strains of indicated organisms.
‡Breakpoints listed in prescribing information: UNASYN, 16 μg/mL (reported as ampicillin concentration); metronidazole, 16 μg/mL; clindamycin, 4.8 μg/mL. Estimated breakpoint for chloramphenicol based on clinical experience, 16 μg/mL.
§Strains used and number of isolates tested were: *Bacteroides fragilis* group, 70; pigmented *Bacteroides* group, 22; other *Bacteroides* sp, 46; *Fusobacterium* sp, 32; *Clostridium difficile*, 10; other *Clostridium* sp, 33; nonsporeforming gram-positive rods, 23; gram-positive cocci, 36.
‖These non-β-lactamase-producing strains are susceptible to ampicillin alone.

BRIEF SUMMARY
UNASYN® (ampicillin sodium/sulbactam sodium) IM/IV, 1.5 and 3g vials

Indications and Usage
UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.

Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*

Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*

Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).

*Efficacy for this organism in this organ system was studied in fewer than 10 infections.

While UNASYN is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

Contraindications
The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.

Warnings
SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN REPORTS OF INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE. OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

Precautions
General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN, the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.

Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.

Drug/Laboratory Test Interactions: Administration of UNASYN* (ampicillin sodium/sulbactam sodium) will in high urine concentration of ampicillin. High urine concentrations of ampicillin may result in false p reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fe Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clini or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in p concentration of total conjugated estriol, estriolglucuronide, conjugated estrone, and estradiol has been This effect may also occur with UNASYN.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been perfor evaluate carcinogenic or mutagenic potential.

Pregnancy
Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because a reproduction studies are not always predictive of human response, this drug should be used during pregnan if clearly needed. (See—Drug/Laboratory Test Interactions.)

Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreas uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effe the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obst intervention or resuscitation of the newborn will be necessary.

Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, c should be exercised when UNASYN is administered to a nursing woman.

Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under th of 12.

Adverse Reactions
UNASYN is generally well tolerated. The following adverse reactions have been reported:

Local Adverse Reactions
Pain at IM injection site—16%
Pain at IV injection site—3%
Thrombophlebitis—3%

Systemic Adverse Reactions
The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than the patients.

Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting didiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine rete dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis, and m bleeding.

Adverse Laboratory Changes
Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were

Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.

Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and incr lymphocytes, monocytes, basophils, eosinophils, and platelets.

Blood Chemistry: Decreased serum albumin and total proteins.

Renal: Increased BUN and creatinine.

Urinalysis: Presence of RBC's and hyaline casts in urine.

The following adverse reactions have been reported with ampicillin-class antibiotics and can also occu UNASYN.

Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.

Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatiti been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticoste Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician di otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicilli WARNINGS).

Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of th and are believed to be hypersensitivity phenomena.

NEW Unasyn® IM IV

Infection and labor: The detection of endotoxin in amniotic fluid

Roberto Romero, M.D., Nicholas Kadar, M.D., John C. Hobbins, M.D., and Gordon W. Duff, M.D., Ph.D.

New Haven, Connecticut

Intra-amniotic infections are frequently caused by gram-negative organisms. Lypopolysaccharide, or endotoxin, is a component of the cell wall of these bacteria. The *Limulus* amebocyte lysate assay is the most sensitive test clinically available for the detection of endotoxin in biologic samples. The diagnostic value of the *Limulus* amebocyte lysate assay test for the detection of intra-amniotic infection has been examined and compared with that of the Gram stain. The Gram stain had a 60.8% sensitivity and 9.6% false positive rate. The *Limulus* amebocyte lysate assay had a 69% sensitivity and a 4.8% false positive rate. When both tests were used in combination, the sensitivity improved to 95.6%, whereas the false positive rate was 14.3%. The *Limulus* amebocyte lysate assay test is a rapid, sensitive, inexpensive, and simple test for the detection of gram-negative intra-amniotic infections. (AM J OBSTET GYNECOL 1987;157:815-9.)

Acute bacterial intra-amniotic infections are an important cause of perinatal morbidity and death.[1] Although early diagnosis and aggressive treatment are believed to decrease the ill effects of intra-amniotic infection, this goal is frequently difficult to achieve because the infection may not be clinically apparent before delivery in all patients.[2] It is likely that bacterial colonization of the amniotic cavity may be detectable before the appearance of overt clinical signs of infection such as fever, uterine tenderness, maternal and fetal tachycardia, and maternal leukocytosis.[3,4]

Because of the potentially serious consequences associated with delayed diagnosis, several tests for the early diagnosis of intra-amniotic infection have been developed. These include Gram stain examination of amniotic fluid, amniotic fluid leukocyte count, bacterial culture, serum C-reactive protein level, and gas liquid chromatographic analysis of amniotic fluid. Unfortunately, leukocyte count and C-reactive protein levels are nonspecific indicators of infection, the Gram stain is a relatively insensitive test, bacterial culture results are not available immediately, and gas liquid chromatographic analysis requires a costly apparatus.

In those cases in which intra-amniotic infection is associated with a gram-negative organism, the presence of bacterial endotoxin or lipopolysaccharide in the amniotic fluid could be anticipated. A rapid bioassay for lipopolysaccharide has been developed based on the gelation of the lysate of blood cells (amebocytes) of the horseshoe crab, *Limulus polyphemus*.[6] The purpose of this communication is to examine the value of this test for detecting lipopolysaccharide in amniotic fluid as an indicator of intra-amniotic infections.

From the Section of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, and the Department of Pathology, Yale University School of Medicine.

Supported by a grant from the Walter Scott Foundation for Medical Research.

Received for publication April 1, 1987; revised April 27, 1987; accepted May 18, 1987.

Reprint requests: Roberto Romero, M.D., Department of Obstetrics and Gynecology, Yale University School of Medicine, 333 Cedar St., P.O. Box 3333, New Haven, CT 06510-8063.

Material and methods

Amniotic fluid was obtained by amniocentesis from patients with preterm labor, premature rupture of membranes, or clinical suspicion of chorioamnionitis because of fever of unknown origin.

Gram stain examination. Gram stain examination of unspun amniotic fluid was performed by using commercial reagents (crystal violet, saffranin, and Gram's iodine) (Difco Laboratories, Detroit, Michigan) under standard conditions.[7] Stained slides were examined by trained technologists. The presence or absence of microorganisms and white blood cells was noted.

***Limulus* amebocyte lysate assay.** The *Limulus* amebocyte lysate assay was performed by adding 100 μl amniotic fluid to 100 μl *Limulus* amebocyte lysate (Haemachem Inc., St. Louis, Missouri, or Associates of Cape Cod, Woodshole, Massachusetts) and incubating the mixture in a motionless water bath at 37° C for 1 hour. A positive test result was scored when a solid adherent gel was present on inversion of the tube. A positive control (100 pg endotoxin) and a negative control (pyrogen-free water) were run with each assay.

Because the *Limulus* amebocyte lysate assay is a clot

Negative	4	38
Total	18	47

Sensitivity: 14/23 = 60.8%; specificity: 38/42 = 90.4%; positive predictive value = 14/18 = 77.7%; negative predictive value = 38/47 = 80. 8%; percent agreement = 80%; κ index = 0.54 (SE = 0.11); p = <0.00003.

assay and amniotic fluid has recognized thromboplastic properties, we examined samples of this fluid from 76 patients undergoing amniocentesis for lung maturity. Inducers of the gelation of the *Limulus* amebocyte lysate assay were not identified in these culture-negative amniotic fluids.

Criteria for the diagnosis of chorioamnionitis, puerperal endometritis, and neonatal sepsis. Intra-amniotic infection was diagnosed by the presence of a positive amniotic fluid culture. Clinical chorioamnionitis was defined following the criteria proposed by Gibbs et al.[8] The diagnosis required a temperature elevation to 37.8° C and two or more of the following criteria: uterine tenderness, malodorous vaginal discharge, and leukocytosis. Leukocytosis was defined as a white blood cell count >15,000/mm. Endometritis was defined as postpartum temperature elevation to 38° C or higher on two occasions 4 hours apart, excluding the day of delivery, with uterine tenderness, foul-smelling lochia, and no other apparent source of fever. Neonatal sepsis was diagnosed in the presence of a positive culture of blood, urine, or cerebrospinal fluid.

Statistical methods. Diagnostic indexes (sensitivity, specificity, and positive and negative predictive value) for the Gram stain and *Limulus* amebocyte lysate assay were calculated according to previously described formulas.[9] Because the different methods of testing for intra-amniotic fluid infection were carried in the same experimental units, statistical significance tests for correlated samples were used. These test the null hypothesis that the marginal totals of the contingency table are homogeneous (i.e., are samples of the same population). McNemar's test was used for 2 × 2 tables and Cochran's Q statistics (which is distributed asymptotically as a χ^2 with n^{-1} degrees of freedom) for K × 2 tables. The unweighted κ statistic was used as a measure of agreement between two tests performed in the same experimental units.[10] Unlike measures of association in a contingency table, this statistic is corrected for the chance agreement that can be expected to occur given the marginal totals. The Fischer's exact test was employed to explore the relationship between *Limulus* amebocyte lysate assay, culture, and Gram stain results and clinical chorioamnionitis and endometritis.

Results

Sixty-five transabdominal amniocenteses were performed in 65 patients. The indications for amniocentesis were as follows: premature labor (n = 3), premature rupture of membranes (n = 51), and fever (n = 1). Culture, *Limulus* amebocyte lysate assay, and Gram stain results were available for all 65 specimens but in four cases no record was made about the presence or absence of white blood cells.

Intra-amniotic infection, defined as a positive amniotic fluid culture, was present in 23 cases. A single organism was isolated from 15 amniotic fluid specimens as follows: *Hemophilus vaginalis* (four cases), *Bacteroides* species (one case), *Staphylococcus aureus* (two cases), group B streptococcus (one case), *Streptococcus pneumoniae* (one case), *Neisseria gonorrhoeae* (one case), *Peptococcus* species (one case), *Escherichia coli* (one case), *Candida* (one case), *H. influenzae* (one case), and *Mycoplasma* species (one case). Two different organisms were isolated from eight specimens. The following bacteria were isolated: fusobacterium species (two cases), *Gardnerella vaginalis* (four cases), *B. fragilis* (five cases), *S. viridans* (four cases), *Lactobacillus* (one case), *Peptococcus* species (one case), *S. aureus* (two cases), and enterococcus (two cases).

Tables I and II depict the classification of culture-positive and culture-negative specimens on the basis of the *Limulus* amebocyte lysate assay and the presence or absence of bacteria based on the Gram stain.

The presence of bacteria in the Gram stain had a sensitivity of 60.8% and a false positive rate of 9.6%. The *Limulus* amebocyte lysate assay had a sensitivity of 69.5% and a false positive rate of 4.8% (Tables I and II). The agreement between the *Limulus* amebocyte lysate assay and the culture result was 83% and between

Table III. Correlation between the results of Gram stain and LAL of amniotic fluid and culture

	Gram stain result	
	*Correct**	*Incorrect*
LAL		
Correct*	44	10
Incorrect	8	3

LAL, *Limulus* amebocyte lysate assay.

*Correct indicates that the test (LAL or Gram stain) correlated appropriately with the result of amniotic fluid culture.

Table IV. LAL and Gram stain

	Positive	*Negative*	*Total*
Culture			
Positive	22	1	23
Negative	6	36	42
Total	28	37	65

LAL, *Limulus* amebocyte lysate assay.

Sensitivity: 22/23 = 95.6%; specificity: 36/42 = 85.7%; positive predictive value = 22/28 = 71.4%; negative predictive value = 36/37 = 97.2%; κ index = 0.77 (SE = 0.08); p = <0.00003.

the Gram stain and the culture result 80%. Table III shows how the *Limulus* amebocyte lysate assay and the Gram stain agreed with the culture result for each of the 65 samples on which both tests were carried out. The difference between the two tests was not statistically significant (McNemar's test).

When the results of the two tests were combined so that a positive Gram stain was indicative of intra-amniotic infection, regardless of the *Limulus* amebocyte lysate assay result, and a positive *Limulus* amebocyte lysate test indicative of intra-amniotic infection, regardless of the Gram stain result (a decision that was made a priori), the sensitivity increased to 95% whereas the false positive rate was 14.3% (Table IV).

The *Limulus* amebocyte lysate test is expected to detect gram-negative organisms. Because endotoxin is present only in gram-negative bacteria, false negative results might occur with intra-amniotic infections caused by gram-positive bacteria, mycoplasmas, and fungi. Table V displays *Limulus* amebocyte lysate results according to taxonomic classification and staining properties. The *Limulus* amebocyte lysate assay detected 33.3% (2/6) pure gram-positive infections whereas it was positive in 80% (12/15) of infections including a gram-negative organism (mixed infections and those including only gram-negative organisms). Of interest is that both *Candida* and *Mycoplasma* infections yielded a positive *Limulus* amebocyte lysate assay.

Three patients had false positive *Limulus* amebocyte lysate test results. All of them had premature rupture of membranes and went into labor within 24 hours of amniocentesis. None had clinical evidence of chorioamnionitis or postpartum endometritis nor their infants neonatal sepsis. In one case a Gram stain was positive for bacteria but culture failed to grow any organisms.

Chorioamnionitis was diagnosed in 26% (17/65) of cases, endometritis in 14.2% (8/56) of cases (nine patients with preterm labor were discharged undelivered; 56 + 9 = 65), and neonatal sepsis in only one case. The infant had a cerebrospinal fluid culture positive for *S. pneumoniae*. In this case the amniotic fluid had a positive Gram stain, the *Limulus* amebocyte lysate assay was negative, and the culture of amniotic fluid was positive for *S. pneumoniae*.

Table VI describes the relationship between Gram stain, *Limulus* amebocyte lysate assay, culture, and the presence of clinical chorioamnionitis and postpartum endometritis. A positive Gram stain or culture was associated with a higher incidence of clinical chorioamnionitis (Gram stain, p = 0.0031; culture, p = 0.0067; Fischer's exact test), whereas the *Limulus* amebocyte lysate assay was not (p = 0.127). On the other hand, the result of *Limulus* amebocyte lysate assay and culture (but not of the Gram stain) correlated with the presence of postpartum endometritis (Gram stain, p = 0.20; *Limulus* amebocyte lysate, p = 0.019; culture, p = 0.0002; Fischer's exact test).

Comment

Accumulating evidence suggests a role for infection in the cause of premature rupture of membranes and preterm labor. Several authors have proposed the use of amniocentesis for bacteriologic examination of the amniotic fluid in these circumstances.[3-5] Because culture results are not available immediately, initial management decisions are based on the Gram stain examination. A limitation of this approach is that the Gram stain examination of amniotic fluid is an insensitive technique detecting only 60% of all positive intra-amniotic infections.[17] This is a serious drawback because infants born to a mother with a false negative Gram stain have a similar rate of neonatal sepsis as that of infants with a true positive Gram stain.[17] Therefore, more sensitive methods for the rapid detection of bacteria in amniotic fluid are required.

Gram-negative organisms are frequently found in intra-amniotic infections. Their cell walls contain lipopolysaccharide, which can be detected as part of the intact cell wall or free after bacterial lysis. The *Limulus* amebocyte lysate assay test is the most sensitive technique currently available for detection of lipopolysaccharide in clinical specimens.[11] It can detect quantities of lipopolysaccharide as low as 5 pg/ml in water and 50 pg/ml in amniotic fluid.[12]

Our data show that the Gram stain and the *Limulus*

Table V. Gram stain and *Limulus* amebocyte lysate assay results according to taxonomic classification of organism and culture result

*For endometritis only 56 patients are considered. Nine patients with preterm labor were discharged undelivered (56 + 9 = 65).

amebocyte lysate assay have comparable diagnostic performance, but when used in combination there is remarkable improvement in sensitivity from 60.8% (Gram stain alone) to 95%. Furthermore, the negative predictive value increased from 80% (Gram stain alone) to 97% when both tests are negative.

Although the *Limulus* amebocyte lysate assay test would be expected to detect only gram-negative organisms, our data indicate that the test result was positive in 33% of pure gram-positive infections and also in cases of *Mycoplasma* or *Candida* intra-amniotic infection. Two possible explanations can be invoked. The infection could have included gram-negative organisms that were not grown in culture because of their fastidious nature or because they were not viable. In the latter case, free lipopolysaccharide released at the time of cell death could give a positive *Limulus* amebocyte lysate assay test result, although the organism may not grow in culture. An alternative explanation is that cross-reacting material induced gelation of the *Limulus* lysate. For example, peptidoglycans, a component of gram-positive bacteria, has been reported to produce a positive *Limulus* amebocyte lysate assay test result.[13] A similar observation has been made with mannan, a carbohydrate molecule isolated from *Candida* species.[14] Although the concept of cross-reactivity may be appealing because of its potential for broadening the spectrum of detectable organisms, this argument can also be spurious. The amount of peptidoglycans required to induce a positive *Limulus* amebocyte lysate assay test result is 400,000 times greater than that of lipopolysaccharide. In other words, contamination of the preparation with as little as 0.00025% of lipopolysaccharide could account for this finding. Such a minute degree of contamination cannot be ruled out in any "purified" material at present.[11]

Amniotic fluid culture has been used as the "gold standard" for the diagnosis of intra-amniotic infection in this study. Thus, one patient with a positive Gram stain and *Limulus* amebocyte lysate assay but a negative culture has been considered to have a false positive result for both techniques. This patient had severe pathologic chorioamnionitis and delivered a premature infant with subsequent negative neonatal cultures. Whether this case represents a false negative bacteriology culture is impossible to ascertain. The dilemma of the selection of an optimal standard is not a new problem in clinical diagnostic testing. Although overt clinical chorioamnionitis could be used as a standard, this would seem inappropriate because the goal of diagnostic testing is the early detection of infection before overt clinical disease.

Our findings that a positive amniotic fluid culture is associated with postpartum endometritis confirm pre-

vious observations of other investigators. Not surprisingly, a positive *Limulus* amebocyte lysate assay correlated with the presence of postpartum endometritis. We were puzzled by the lack of correlation between a positive *Limulus* amebocyte lysate assay and clinical chorioamnionitis and a positive Gram stain and postpartum endometritis. The former observation is probably because the *Limulus* amebocyte lysate assay detects primarily gram-negative bacteria. Indeed, it has a false negative rate of 50% in pure gram-positive infections occurring in patients who are at risk for clinical chorioamnionitis. The latter finding can be attributed to aggressive antibiotic therapy for all patients with a positive Gram stain for bacteria because this approach reduces postpartum endometritis.

Of practical importance is that the *Limulus* amebocyte lysate assay test is inexpensive (reagent cost is approximately $3), rapid, simple, and commercially available.

The detection of lipopolysaccharide in amniotic fluid has important scientific implications because endotoxins are a group of molecules with important biologic effects. Among their properties are the stimulation of prostaglandin release from macrophages and monocytes[15] and also the release of tissue factor from mononuclear cells.[16] These effects could play a role in the onset of labor or the activation of the hemostatic system in the setting of chorioamnionitis.

We conclude that the *Limulus* amebocyte lysate test is a sensitive, inexpensive, rapid, and simple technique for the detection of gram-negative bacteria in amniotic fluid that when used in conjunction with the Gram stain can significantly improve the detection of subclinical intra-amniotic infections.

Maternal serum α-fetoprotein screening

III. Pitfalls in evaluating black gravid women

James N. Macri, Ph.D., Ramana V. Kasturi, B.E., M.S., Mannshya G. Hu, Ph.D., David A. Krantz, B.S., Timothy J. Douros, Paul Sajda, and Edward J. Cook, Ph.D.
Carle Place, New York

Maternal serum α-fetoprotein levels are higher in black women. Misinterpretation of maternal serum α-fetoprotein screening results can subject black gravid women to unnecessary invasive diagnostic procedures and their calculable risks. Screening errors for black women can result from the use of normative data bases established with maternal serum samples drawn from other racial groups or the use of such data bases in conjunction with a published correction factor. Because the incidence of open neural tube defects is lower for blacks than for others, excessive false positive results for blacks (estimated to be 8817 to 28,215 cases annually) would be a pernicious misapplication of maternal serum α-fetoprotein screening. We address the problem outlined above and recommend independently developed, valid, normative data bases. (AM J OBSTET GYNECOL 1987;157:820-2.)

Key words: α-Fetoprotein, pitfalls, black gravid women

It is a physiologic fact that maternal serum α-fetoprotein levels are higher in black gravid women* than in other racial groups.[1-3] Maternal serum α-fetoprotein screening of blacks according to a normative data base established with blood samples drawn predominantly from other racial groups will subject blacks to an increased rate of false positive results. Because maternal serum α-fetoprotein levels are clinically significant in the high range[4] and may be so in the low range,[5] there exists a high probability of erroneous interpretation of maternal serum α-fetoprotein levels for blacks.

In reporting on a Connecticut maternal serum α-fetoprotein screening program, Baumgarten,[3] indicated that between 1981 and 1985, black gravid women demonstrated elevated maternal serum α-fetoprotein levels at more than double the rate (9.5%) of white gravid women (4.4%). This author indicates that maternal serum α-fetoprotein concentrations appear to be distributed differently between black and white racial groups and a higher multiple of the median may be required to exclude (from invasive diagnostic procedures) a similar percentage of blacks as whites in screening for open neural tube defects. Baumgarten points out that misinterpretation of data can follow omission of race as a factor in the assessment of maternal serum α-fetoprotein levels.

**Blacks are defined in this study as persons who have designated themselves as such. Additional subgroup evaluation is underway.*

Table I. Racial differences* in median maternal serum α-fetoprotein levels

Gestation (wk)†	No. of Patients		% Difference of medians (black − white) / white
	Black	White	
15	295	761	16.6
16	568	1984	21.3
17	437	1549	21.6
18	337	827	2.8
19	203	396	17.6
20	114	180	−1.5

*These differences are based on median maternal serum α-fetoprotein levels without maternal weight adjustment. We applied three methods of maternal weight adjustment[7] that resulted in increased percentage differences between black and white median maternal serum α-fetoprotein levels.

†The mean gestational age for whites = 16.8 weeks; the mean gestational age for blacks = 17.0 weeks.

In comparing maternal serum α-fetoprotein levels between blacks and other racial groups, others have found that on the average blacks demonstrated a 10% increased level in weeks 14 to 22 of gestation.[1,2] Based on these findings and in an effort to correctly interpret maternal serum α-fetoprotein levels in black gravid women, the use of a 10% uniform correction factor (for gestational weeks 14 to 22) has been recommended to be applied to maternal serum α-fetoprotein levels in black gravid women.

Analysis of data

We have evaluated data (both our own and currently available data in the literature) comparing racial dif-

Table II. Projected maternal serum α-fetoprotein interpretations in the total black pregnant population in the United States (based on data generated from this study)

*Maternal serum α-fetoprotein interpretation**	*Method 1: use of black maternal serum α-fetoprotein medians*	*Method 2: use of white maternal serum α-fetoprotein medians*	*Method 3: use of 10% adjusted black values with white maternal serum α-fetoprotein medians*
Within normative range	547,830	519,615	539,013
Borderline elevation	22,336 (3.8%)	35,268 (6%)	25,275 (4.3%)
Significant elevation	17,634 (3.0%)	32,917 (5.6%)	23,512 (4.0%)
Total	587,800†	587,800	587,800

*The maternal serum α-fetoprotein interpretation is based on patient-specific risks.[4] Data presented pertain to maternal serum α-fetoprotein screening for structural malformations. Effect of race on Down's syndrome screening is under investigation.

†Total number of black births in the United States.[8]

ferences in levels of maternal serum α-fetoprotein. In a report from Crandall et al.,[1] individual weekly differences varied from as low as −4% to as high as 20%. Similarly, data from Baumgarten[3] demonstrate differences varying from 1% to 22%. Although a statistical analysis of available data might reveal an average 10% racial differential, careful evaluation of individual weekly differences indicates that the application of a uniform correction factor to maternal serum α-fetoprotein levels in blacks may indeed be inaccurate.

We have compared maternal serum α-fetoprotein levels between 5697 unaffected white and 1954 unaffected black pregnancies. Table I confirms previous observations that the percent difference of maternal serum α-fetoprotein medians between black and white gravid women varies with each week of gestation. However, what has not been reported previously, is that the variances of the black and white maternal serum α-fetoprotein distributions (based on log multiple of the median*) differ significantly.† If it is valid to interpret black maternal serum α-fetoprotein data by use of a 10% correction factor, these two distributions should be coincident. The significant difference in variance invalidates the use of this correction factor. Of additional interest is our observation that data presented by Baumgarten[3] (when analyzed by us) demonstrate a similar significant difference in variance between black and white maternal serum α-fetoprotein distributions.

Table II contrasts three methods of evaluating maternal serum α-fetoprotein values in black gravid women. Use of method 1 yields the lowest number of false positive results. With method 2, 70.6% more black gravid women will be informed of elevated maternal serum α-fetoprotein levels, indicating increased risk and counseling for further testing when white medians are used. With method 3, 22.1% more black gravid women will be counseled for increased risk when a 10% adjusted black value is used. With a valid data base (method 1) for all black gravid women in the United States (based on data generated in this study), false positive interpretations of maternal serum α-fetoprotein values would be reduced by 28,215 cases annually in comparison with method 2 and by 8817 cases annually in comparison with method 3.

*We note that multiple of the median as a statistical parameter of measurement is appropriate, but multiples of the median should not be used for reporting to clinicians or patients.

†The F statistic demonstrated significance of difference in variance ($p < 0.01$).

Comment

When a laboratory has screened a sufficient number of maternal serum α-fetoprotein samples to accumulate a significant sampling of black gravid women, two facts become apparent: (1) the mean of the distribution of maternal serum α-fetoprotein levels in black gravid women is significantly higher than that in other gravid women and (2) the dispersion of the levels in black gravid women is greater than in others. If either of these facts is not taken into account in evaluating maternal serum α-fetoprotein concentrations in black gravid women, black women will be subjected to unnecessary anxiety, expense, inconvenience, and potential maternal or fetal harm. To be spared this adverse clinical experience, it is necessary to evaluate maternal serum α-fetoprotein concentrations in blacks on the basis of a distribution of maternal serum α-fetoprotein levels established in a suitable population of black gravid women.

Because several investigators have reported higher concentrations of maternal serum α-fetoprotein levels in black gravid women, screening laboratories have begun to use a uniform 10% adjustment factor in interpreting black maternal serum α-fetoprotein levels. However, it is clear that although maternal serum α-fetoprotein levels are higher in black gravid women, the amount of difference between black gravid women and others is by no means consistent through successive weeks of gestation. Consequently, the application of any uniform adjustment factor is at best an approximation to physiologic reality and at worst a contribution to false positive findings.

Only when maternal serum α-fetoprotein screening is conducted on an appropriate scale[6] by a competent laboratory will the accumulation of maternal serum α-fetoprotein samples from black gravid women permit the development and use of a normative data base suitable to the population screened. This, in turn, will allow blacks to receive patient-specific risk reports based on relevant normative data.[4]

Amniotic fluid α-fetoprotein levels and pregnancy outcome

Cynthia G. Brumfield, M.D., Gretchen A. Cloud, M.S., Sara C. Finley, M.D., Paula Cosper, Ph.D., Richard O. Davis, M.D., and John F. Huddleston, M.D.

Birmingham, Alabama

Elevated and low levels of maternal serum α-fetoprotein in the midtrimester of pregnancy have been linked with adverse events in later gestation, such as fetal and neonatal deaths, chromosomal abnormalities, and low birth weight infants. It is not known if this same association with poor pregnancy outcome is also true of amniotic fluid α-fetoprotein. In this study, α-fetoprotein was obtained from the fluid of 1060 women undergoing genetic amniocentesis for advanced maternal age. Poor pregnancy outcome was defined as (1) a fetal or neonatal death, (2) preterm delivery, or (3) low birth weight infants. Amniotic fluid α-fetoprotein was compared to each type of adverse outcome. No significant association with a poor pregnancy outcome in later gestation was noted. Although serum α-fetoprotein in the midtrimester of pregnancy may relate to certain poor outcomes in later gestation, midtrimester amniotic fluid α-fetoprotein offers no predictive value for the course of events in later gestation. (Am J Obstet Gynecol 1987;157:822-5.)

Key words: Amniotic, α-fetoprotein, pregnancy outcome

Elevated α-fetoprotein levels in maternal serum and amniotic fluid from the midtrimester of pregnancy are known to be associated with the presence of certain fetal anomalies, such as open neural tube defects, fetal abdominal wall defects, and cystic hygromas.[1] Recently the opposite end of the α-fetoprotein–screening spectrum, the low serum level, has been associated with chromosomal abnormalities,[2] and amniotic fluid α-fetoprotein levels have been found to be decreased in fetuses with Down's syndrome.[3]

In addition to aiding in the detection of fetal defects, abnormal maternal serum α-fetoprotein levels have been linked with adverse events occurring in later gestation. Elevated serum levels have been noted with fetal deaths, low birth weight infants, and neonatal deaths,[4] and low levels of maternal serum α-fetoprotein have been associated with an increased likelihood of a second-trimester fetal loss.[5] It has not been ascertained whether amniotic fluid α-fetoprotein levels in the midtrimester of pregnancy, like its serum counterpart, can predict subsequent adverse outcomes later in gestation. To address this question, our genetic amniocentesis data were reviewed retrospectively for a 2-year period to determine if a correlation existed between amniotic

fluid α-fetoprotein values and subsequent adverse pregnancy outcomes.

Material and methods

The records of patients referred for prenatal diagnosis to the Laboratory of Medical Genetics at the University of Alabama at Birmingham from January 1, 1983, through December 31, 1984, were reviewed retrospectively. The prenatal diagnosis program is a collaborative effort between the Department of Obstetrics and Gynecology, which provides diagnostic ultrasonographic and amniocentesis services, and the Laboratory of Medical Genetics, which provides genetic counseling and laboratory services. The patient population consisted of private referrals from physicians in the southeastern United States, primarily from Alabama, Mississippi, Tennessee, Georgia, and Florida. The patients referred were primarily white (85%) and 93% were private referrals. Only 7% of patients seen were indigent referrals from county health departments in the state of Alabama.

Each patient underwent genetic counseling by a clinical geneticist before undergoing amniocentesis. Amniotic fluid α-fetoprotein determination was offered in addition to fetal karyotyping on the amniotic fluid samples obtained. Before each amniocentesis, an ultrasonographic examination was performed to document fetal viability, assess fetal anatomy, confirm gestational age, detect multiple gestation, and choose the amniocentesis site. Transplacental puncture was avoided whenever possible. The amniocentesis was performed by standard procedure with a 22-gauge spinal needle. Cytogenetic studies were performed at the Laboratory of Medical Genetics according to standard technique. All amniotic fluid α-fetoprotein samples were analyzed by the same reference laboratory (Aubrey Milunsky, Boston, Massachusetts), and determinations were performed by rocket electroimmunodiffusion, for which the normal range at each second trimester week have been published.[6]

Six months after the amniocentesis was performed a letter requesting follow-up data on each patient was mailed to each referring physician or county health department. The letter consisted of a series of questions asking whether any complications occurred immediately after the amniocentesis or later during the course of pregnancy. The date of birth, the infant's sex, birth weight, gestational age at birth, type of delivery, and whether any complications occurred at delivery or during the neonatal course were also asked in the questionnaire. If no response was obtained to the letter, a phone call was made to the physician's office or health department to obtain the requested information. If accurate follow-up data were still missing, phone calls were made to the patient's residence.

Table I. Mean α-fetoprotein levels at week of gestation studied with 95% confidence intervals

Week of gestation	*α-Fetoprotein (mg/dl)*
15	1.03 ± 0.070
16	1.03 ± 0.028
17	0.97 ± 0.039
18	0.85 ± 0.067
19	0.74 ± 0.072
20	0.77 ± 0.224

This study was restricted to patients who were undergoing the procedure because of advanced maternal age (≥35 years at delivery) and who had a singleton pregnancy between 15 and 20 weeks' gestation. Only patients with no serious medical problems and who underwent the procedure at our institution and by our physicians were included. Any patients who had a nonviable or structurally abnormal fetus at the time of the ultrasonographic examination or who later were found to have fetal chromosomal abnormality were excluded. Those patients who did not have both fetal karyotyping and α-fetoprotein determination of the amniotic fluid drawn at amniocentesis or complete follow-up information after delivery were excluded.

All records that met the criteria for inclusion in this study were reviewed retrospectively. The patient's age, race, parity, the color of the fluid at amniocentesis, and the best estimate of gestational age were recorded. If the menstrual dates were considered reliable and the average ultrasound measurements were within 10 days of the menstrual dates, the menstrual age was used to date the pregnancy. If there was a doubt as to the last menstrual period or if the ultrasonographically determined age varied by >10 days from the menstrual age, the gestation by ultrasound was used to date the pregnancy. The fetal karyotype and amniotic fluid α-fetoprotein values were recorded on each patient and then matched with the letter containing follow-up information from each pregnancy.

Poor pregnancy outcome was defined as: (1) fetal or neonatal death, (2) delivery before 37 completed weeks of gestation, or (3) delivery of an infant weighing ≤the tenth percentile for its expected gestation (low birth weight). Tenth percentile birth weights at each gestation were calculated from data published previously and determined from abortuses and infants delivering at sea level.[7] Because of the large number of private physicians participating in the prenatal care and delivery of these infants, we were unable to include the prenatal management, mode of delivery, Apgar scores, or presence of fetal distress into consideration for factors predicting adverse pregnancy outcome.

*By analysis of covariance.

There were 1060 women with singleton pregnancies and complete follow-up information who underwent genetic amniocentesis for advanced maternal age at our institution from January 1, 1983, through December 31, 1984. There were 159 primigravid and 901 multiparous women. Nine hundred one women were white (85%) and the median maternal age of the study group was 36 years.

The Student t test and χ^2 analyses were used to correlate maternal factors and results with pregnancy outcomes. A p value ≤ 0.05 was considered significant. Standard analysis of variance and covariance analysis of variance techniques were used to determine any significant maternal age and α-fetoprotein relationship for the different complications at birth. Duncan's multiple range test was used for all multiple comparisons. The Kolmogorov-Schmirnoff test of goodness of fit was used to determine if the data constituted a random sample from a normal population.

Results

No statistically significant differences were noted between primigravid and multiparous women and between different racial groups in the study population when each was compared to the level of amniotic fluid α-fetoprotein. Four hundred forty-four women in this study were ≤36 years of age and 152 women were ≥39 years of age. There was no difference in amniotic fluid α-fetoprotein levels when compared to these extremes of maternal age in this study. One thousand eight patients had α-fetoprotein values ±2 SD within the mean at each gestational age. Forty-three were >3 SD above the mean at any given gestational age. Two patients had α-fetoprotein values as high as 5 SD above the mean. No α-fetoprotein values fell as low as 2 SD below the mean for a given gestational age.

Sixty-six (6%) women were delivered before 37 weeks' gestation, 34 (3%) had low birth weight infants, and 21 (2%) had fetal or neonatal deaths. The fetal deaths were the result of unexplained causes and the neonatal deaths were primarily caused by extreme prematurity. Eleven patients had losses in the second trimester and 10 deaths were near term.

Two different statistical analyses were used to compare amniotic fluid α-fetoprotein with each type of poor pregnancy outcome. Table I illustrates the 95% confidence intervals for amniotic α-fetoprotein at each week of gestation. Table II depicts the statistical lack of correlation by analysis of covariance using week of sampling as the covariant. The least-square mean α-fetoprotein levels were lower in those patients who later were found to have a fetal or neonatal death but not in those patients delivering low birth weight infants or preterm infants. Although this finding is an interesting trend, it did not reach statistical significance. Table III shows the wide variation in amniotic fluid α-fetoprotein levels with each type of poor outcome. Amniotic fluid α-fetoprotein levels could not be used to predict a later adverse outcome because of their wide overlapping with values in patients with normal outcomes.

Thirty-six patients (3%) had discolored fluid at amniocentesis. Our laboratory does not routinely test for fetal hemoglobin unless an α-fetoprotein values exceeds 3 SD above the mean. One patient with discolored fluid had a value above 3 SD but did not have fetal hemoglobin in the amniotic fluid sample. Discolored fluid was not statistically associated with a poor pregnancy outcome.

Comment

The physiology of amniotic fluid α-fetoprotein has been described extensively.[8] During normal pregnancy amniotic fluid α-fetoprotein follows a decreasing pattern similar to that of fetal serum and is contributed to normal amniotic fluid by fetal urination. In this study, 1060 women undergoing genetic amniocentesis for advanced maternal age were offered and chose to have α-fetoprotein determination on the amniotic fluid samples obtained. Fetal structural abnormalities and patients with medical problems were excluded from analysis of the final data. The amniotic α-fetoprotein values

were in a range similar to what has been reported in other populations studied.[9]

Our patients were primarily white middle-class women from the southeastern United States. They were private referrals and all were in excellent health. The outcomes of their pregnancies were generally good and were similar to what has been published about other populations in the advanced maternal age range.[10] Although low and elevated serum α-fetoprotein levels have been linked to adverse outcomes in later gestation, no one to date has published a study comparing amniotic fluid α-fetoprotein levels with later pregnancy outcomes. However, we could find no statistical correlation between amniotic α-fetoprotein values and a later poor pregnancy outcome. In our study population, patients who later had a poor pregnancy outcome had α-fetoprotein values within the normal range and thus too closely overlapped those with normal outcomes to be of any predictive value.

If a correlation with adverse events in later pregnancy is found with abnormal levels of maternal serum α-fetoprotein, then why is there no such finding with amniotic fluid α-fetoprotein levels? It has not been clearly defined yet how α-fetoprotein passes from the fetal compartment into the maternal serum. It has been suggested[11] that the placenta or amnion regulates this protein interchange. Thus a genetically abnormal or physiologically compromised placenta in the midtrimester of pregnancy would cause abnormal α-fetoprotein levels in maternal serum. Because α-fetoprotein enters the amniotic fluid presumably by fetal urination after the fourteenth week of gestation, placental insufficiency from whatever cause would have no bearing on the amount of α-fetoprotein in the amniotic fluid with α-fetoprotein levels remaining within the normal range.

In summary, amniotic fluid α-fetoprotein in the midtrimester of pregnancy has no correlation with later preterm births, fetal or neonatal deaths, or low birth weight infants. A normal α-fetoprotein value obtained at genetic amniocentesis is reassuring that no major fetal structural defect associated with elevated amniotic fluid α-fetoprotein is present at the time of sampling but offers no predictive value to the course of events for that pregnancy in later gestation.

Cord serum bromide concentration: Variation and lack of association with pregnancy outcome

Marvin E. Miller, M.D., Janice M. Cosgriff, B.S., and Klaus J. Roghmann, Ph.D.
Rochester, New York

Excessive maternal bromide exposure during pregnancy from drugs and occupation have been reported to have adverse effects on the fetus and newborn, including central nervous system depression at birth and possible teratogenicity. To define further the fetal bromide exposure during pregnancy, we determined the cord serum bromide concentration in 1267 newborn babies born in Rochester, New York, during the 6-month period from January 1, 1984 to June 30, 1984. There was a normal distribution of the cord serum bromide concentration values ($\bar{X} \pm SD = 8.6 \pm 2.6$ mg/L; range 3.1 to 28.5 mg/L). The highest concentration was still significantly below the minimal bromide concentration associated with toxic effects (720 mg/L). There was no association between the cord serum bromide concentration and indices of fetal health including Apgar scores, presence of congenital malformations, and neonatal disposition. No mothers were taking significant amounts of bromide-containing drugs during pregnancy. The second highest cord serum bromide concentration (21.4 mg/L) was in a woman who was an amateur photographer and developed her own film, which required her to use chemicals containing bromide. Our results indicate that excessive fetal bromide exposure is rare and probably occurs only in the setting of maternal use of bromide-containing drugs or occupational exposure during pregnancy. (Am J Obstet Gynecol 1987;157:826-30.)

Key words: Bromide, cord blood, pregnancy, outcome

Bromide is normally present in low concentrations in water and many foods.[1] Several reports of excessive maternal bromide exposure during pregnancy have indicated adverse effects on the fetus and newborn infant.[2-6] These maternal exposures were from bromide-containing drugs and occupational exposure to bromide-containing salts in the photographic industry. To study the issue of fetal bromide exposure during pregnancy further, we determined the cord serum bromide concentration in a cohort of newborn infants born at a tertiary care hospital to determine the variation in concentrations and whether there was any correlation between the cord serum bromide concentration and pregnancy outcome. Performing this study in Rochester, New York, where the largest photographic manufacturing and developing company in the United States is located (Eastman Kodak), provides the greatest possibility of detecting occupational exposure to bromides causing elevated cord serum bromide concentration.

Methods

Specimen collection. Five milliliters of cord blood was drawn from babies born at Strong Memorial Hospital, Rochester, New York, between January 1, 1984, and June 30, 1984. The cord serum was recovered and placed in a plastic tube and stored at −70° C until analyzed.

We also obtained maternal blood specimens at the time of delivery in 20 obstetric patients and the corresponding cord blood specimen from their baby, so that bromide concentrations in each could be determined and compared.

Bromide analysis. The bromide concentration was determined in serum ultrafiltrate of each cord blood and maternal blood specimen by use of a previously described anion-exchange chromatographic method.[7] Serum ultrafiltrate was obtained by centrifugation of 1 ml of serum in an Amicon MPS micropartition system at 2000 × g for 25 minutes.

The chromatography system was a Varian 5020B with a UV-100 variable wavelength detector interfaced with a Varian 4270 integrator. A Whatman Partisil-10 SAX 250 by 4.6 mm inside diameter anion exchange column was used with 30 mmol/L KH2P04 mobile phase at a flow rate of 0.7 ml/min. The detection wavelength was 200 nm and the injection volume was 5 μl. Under these conditions the retention time of the bromide peak was about 11.5 minutes. The serum ultra-

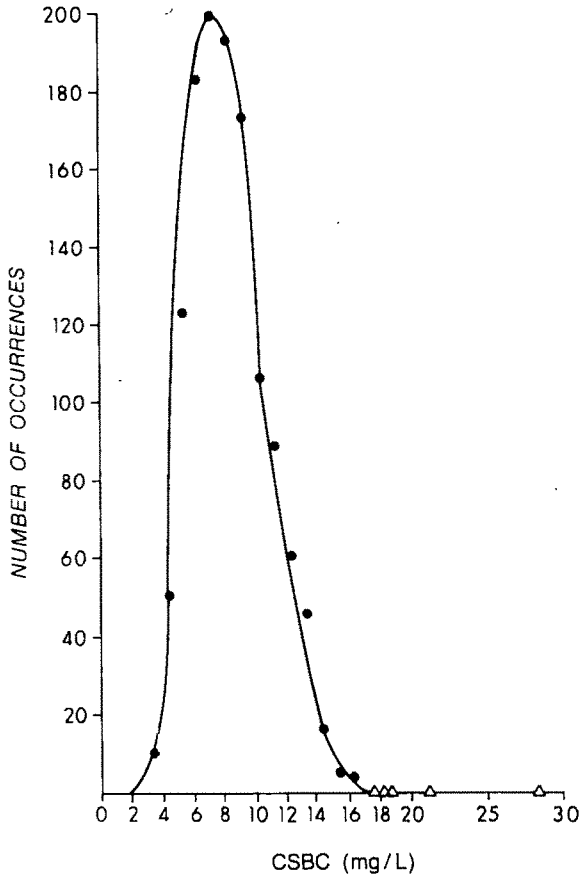

Fig. 1. Frequency distribution of cord serum bromide concentration *(CSBC)* in 1267 specimens. Each point represents the number of occurrences of cord serum bromide concentration between integral values of the concentration plotted at midinterval, in that the number of occurrences between 3 and 4 mg/L is plotted at 3.5 mg/L, the number of occurrences between 4 and 5 mg/L is plotted at 4.5 mg/L, and so forth. The *triangles* represent individual values of the five highest cord serum bromide concentrations.

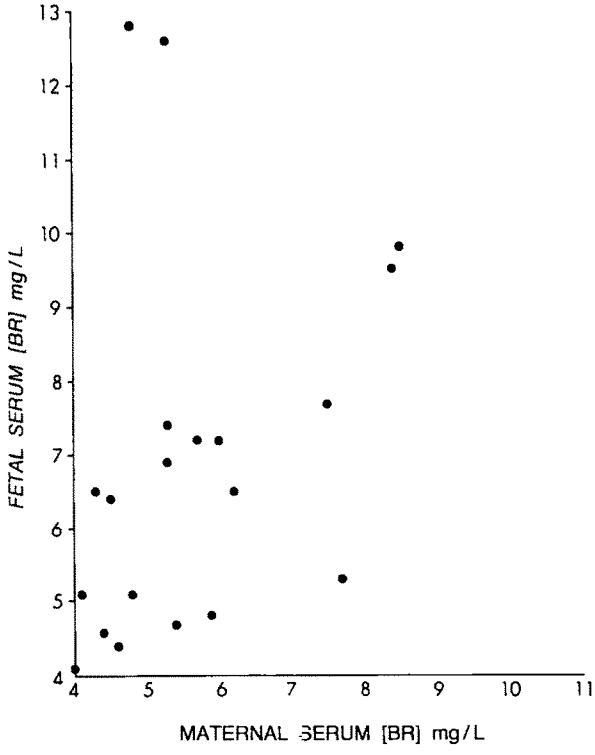

Fig. 2. Scatter plot of maternal serum versus fetal serum bromide concentration *([BR])*. There was general agreement between the two values, with the fetal serum bromide concentration level tending to be slightly greater. There is no obvious explanation for the two points that indicate a significantly higher fetal than maternal serum bromide concentration. The correlation coefficient is 0.33, and is 0.71 when the two discrepant values are excluded.

filtrate concentration was determined by the area under the curve as compared with those of known bromide standards for which absorbance was linear from 1 to 1000 mg/L.

Because serum is 93% water, the cord serum bromide concentration is 0.93 × the cord serum ultrafiltrate bromide concentration.

Data collection and analysis. Data about every obstetric admission and delivery at Strong Memorial Hospital are kept at The Perinatal Data Registry of the Rochester Regional Perinatal Center. The following information for each pregnancy and baby was abstracted from the registry: race of the mother, presence of hypertension in the mother, radiation exposure during pregnancy, drug exposure during pregnancy, maternal occupational history, neonatal outcome (stillborn, death during perinatal period, or live born and discharged home), resuscitation required after delivery, Apgar score at 1 minute, Apgar score at 5 minutes, presence of congenital malformation(s), newborn temperature, newborn respiration rate, newborn pulse, and newborn weight. Mothers were asked about drug usage during pregnancy but not specifically about bromide-containing drugs. The relationship of each of these variables to the cord serum bromide concentration was tested by scatter plots, correlation coefficients, and, for categorical variables, one-way analysis of variance. The cord serum bromide concentration and maternal bromide serum concentration at delivery were compared by determining the absolute percent agreement [(lower of the two values/higher of the two values) × 100%] and by determining the correlation coefficient between them.

Results

During the 6-month period, cord blood specimens for determination of cord serum bromide concentration were available from 1267 of the 1591 babies born at Strong Memorial Hospital. The range of the con-

Table I. Cases of maternal bromide exposure causing adverse fetal effects

Case	*Patient's age*	*Neonatal history*	*Maternal exposure*	*Bromide determination**
Mangurten and Kaye[2]	Newborn (43 wk)	Cyanosis, hypotonia, poor feeding, dysmorphic face	Worked in photographic laboratory	Baby's urine (day 14): 330 mg/L Mother's serum (day 18): 190 mg/L Baby's serum (day 18): 150 mg/L
Mangurten and Ban[3]	Newborn (37 wk)	Weak cry, poor suck, hypotonia	6 gm bromide per day	Mother's serum (day 5): 3100 mg/L Baby's serum (day 5): 2000 mg/L Baby's urine (day 5): 1660 mg/L
Pleasure and Blackburn[4]	Newborn	Hypotonia	Nervine tablets	Mother's serum (day 4): 2150 mg/L Baby's serum (day 5): 2420 mg/L
Finken and Robertson[5]	Newborn (39 wk)	Lethargy	Nervine tablets	Baby's serum (day 7): 3650 mg/L
Opitz et al.[6] (siblings)	a. 8 yr b. 7 yr	a. Growth deficiency b. Growth deficiency; congenital heart disease	Chronic ingestion of Bromo-Seltzer	Mother's serum: 1350 mg/L

*Normal values[2]: urine bromide concentration <2.5 mg/L; serum bromide concentration <20 mg/L.

centration was 3.1 to 28.5 mg/L, with a mean of 8.6 mg/L and a standard deviation of 2.6 mg/L. The standard error of the mean is therefore only 0.073 mg/L, and the 95% confidence interval around the mean is between 8.46 and 8.74 mg/L. The frequency distribution of the cord serum bromide concentrations is shown in Fig. 1. There was no significant deviation of this distribution from a normal distribution as measured by kurtosis or skewness.

Statistical testing of the cord serum bromide concentration against the 14 parameters mentioned above showed no significant findings. Noteworthy was that the mother of the baby with the second highest cord serum bromide concentration (21.4 mg/L) was an amateur photographer who developed her own photographs at home.

A scatter plot of the 20 paired maternal serum and cord serum values for bromide concentration is shown in Fig. 2. The two values tended to be similar, with the cord serum bromide concentration tending to be a little higher than the mother's serum bromide concentration. The absolute percent agreement between the two values was 78%. The correlation coefficient between these two measurements was 0.33; when the two discrepant values in the upper left corner were excluded, however, the correlation coefficient was 0.71.

Comment

At least four case reports of neonatal bromism secondary to maternal ingestion or exposure to bromide-containing compounds during pregnancy have been published (Table I).[2-5] The cardinal features in these babies were weakness and hypotonia. Maternal exposure in three cases was from the use of bromide-containing drugs during pregnancy and in one case from a presumed occupational exposure to bromide salts in the photographic developing industry. In addition, Opitz et al. described two siblings with significant postnatal growth deficiency who were born to a mother who had been taking the bromide-containing drug Bromo-Seltzer during both of these pregnancies (Table I).[6] (Bromo-Seltzer contained bromide before 1972 but no longer does.) One of the affected children also had congenital heart disease. The mother took no Bromo-Seltzer during the pregnancies of three other healthy siblings who were of normal stature. This observation raises the question of potential teratogenic effect of bromide exposure during pregnancy.

There are four possible sources of bromide exposure that could lead to systemic absorption and accumulation: drugs, occupational exposure, food, and water. Bromide is found in very small quantities in food and water. To the best of our knowledge, no cases of human bromism have been reported from the ingestion of either food or water of high bromide content.

The use of bromide-containing drugs in the United States has significantly decreased in the past 25 years, and there are few, if any, prescription drugs that now contain significant amounts of bromide. Bromide formerly enjoyed widespread use as an anticonvulsant drug and in nonprescription sedatives.[8] However, bromide has a long biologic half-life (12 days), and thus

prolonged administration of bromide can lead to bromide toxicity. Bromide-containing drugs have therefore almost entirely been removed from the market.[9] Thus it is not surprising that in our population of over 1200 mothers we found none with a history of bromide-containing drug use.

There is little information on occupational exposure to bromides causing bromide accumulation in exposed individuals. There is one reported case of neonatal bromism from occupational exposure to bromides.[2] Mangurten and Kaye (case 1; Table I) reported a 25-year-old pregnant woman who, although denying the use of bromide-containing drugs, was found to have an elevated serum bromide level 18 days after the birth of her baby, who had clinical signs of neonatal bromism with significant unexplained hypotonia and generalized central nervous system depression. The baby had a serum bromide level of 150 mg/L on the eighteenth day of life and had a markedly elevated concentration of bromide in the urine. The mother's occupational history revealed that she had worked in a photographic laboratory until 5 weeks before delivery. She mixed photographic developing chemicals containing sodium bromide and potassium bromide on a daily basis. Those authors concluded that the occupational exposure to bromide-containing photographic compounds was the basis of asymptomatic "maternal bromism," which led to symptomatic neonatal bromism. Although it is not clear what the route of exposure was in her case, inhalation, skin absorption, or ingestion of chemical dusts or chemical solutions are all possibilities.

Bromide can penetrate human skin, although it does so at a very slow rate (0.09 to 0.16 mEq/cm^2/min).[10] This absorption rate is similar to those of sodium, potassium, and phosphate. These ions are absorbed to a significant extent through rabbit skin (3 to 8 mEq/cm^2/min), and to a modest extent through pig skin (0.5 to 5 mEq/cm^2/min). The finding that the second highest cord serum bromide concentration (21.4 mg/L) was in a mother who was an amateur photographer and developed her own films suggests that there can be systemic absorption of bromide from handling bromide-containing chemicals used in photographic development. It must be emphasized that while the cord serum bromide concentration in this baby was elevated compared with the mean of this population, it was significantly below what is considered to be a toxic level, namely >720 mg/L.[11]

Bromide is found in low concentrations in food, drinking water, and beverages. In The Netherlands the bromide concentration of vegetables is about 4 mg/kg, milk 3 mg/kg, meat 4 mg/kg, fish 7 mg/kg, and drinking water 0.1 mg/kg.[1] The daily intake of bromide by humans in The Netherlands during the summer of 1976 was 7.8 mg (range 3 to 15 mg) and during the winter of 1978 it was 7.6 mg (range 2 to 17 mg). With this average daily intake of bromide, and assuming that the individual weighs 70 kg, that the volume of distribution of bromide is 0.3 L/kg,[12] and that the bromide half-life is 12 days,[9] the steady-state serum bromide concentration is calculated to be 6.4 mg/L (see Appendix). This is in agreement with the values for mean cord serum bromide concentration and mean adult female serum bromide concentrations we found. These data suggest that the vast majority of bromide found in the average person comes from food, beverages, and water.

Our results indicate that there is some variation in the cord serum bromide concentration, but even the highest value of the more than 1200 specimens studied was significantly below the minimum toxic bromide concentration. The mean value of 8.6 mg/L is 1.2% of the minimum serum bromide concentration associated with toxicity. The large sample size of 1267 specimens gives a large power in the detection of small differences in the order of 10% of the mean value (±0.9 mg/L) or 50% of the standard deviation (±1.3 mg/L). Under the most extreme of these possibilities, the highest mean cord serum bromide concentration would still only be 9.9 mg/L (8.6 + 1.3 mg/L). No mothers appeared to be taking bromide-containing drugs and only one mother who was exposed to bromides from occupational exposure (amateur photographer). This would suggest that there is no fetal risk from bromide exposure in the baby born to a mother who is not taking bromide-containing drugs and who is not exposed to bromides from her occupation. In instances in which mothers are taking bromide-containing drugs or handle photographic developing chemicals during pregnancy, the pediatrician should keep in mind the possibility of bromide toxicity if perinatal problems are encountered.

We are grateful to Dr. Donald Shapiro for his guidance and support.

Calculation of steady-state serum bromide concentration

V_d = volume of distribution of bromide
Cl = clearance of bromide
t½ = half-life of bromide
K_{el} = elimination constant of bromide
$[Br]_{ss}$ = steady-state serum bromide concentration
DI_{Br} = daily intake of bromide

A. Pharmacokinetic relationships

1. $Cl = V_d \times K_{el}$
2. $K_{el} = \frac{0.693}{t_{1/2}}$
3. $[Br]_{ss} = \frac{DI_{Br}}{Cl}$

B. Combining 1, 2, and 3; assume 70 kg individual; assume daily bromide intake in United States is similar to that in The Netherlands

$$[Br]_{ss} = DI_{Br} \times \frac{t_{1/2}}{0.693 \times V_d}$$

$DI_{Br} = \frac{7.7 \text{ mg}}{70 \text{ kg}}$ (reference 1)

t½ = 12 days (reference 9)

V_d = 0.3 L/kg (reference 12)

$[Br]_{ss}$ = 6.4 mg/L

Fetal-induced trauma as a cause of antepartum hemorrhage

John A. Eden, M.R.C.O.G.
London, England

External trauma is a well-known cause of antepartum hemorrhage. These two cases demonstrate that fetal trauma may also be a cause of antepartum hemorrhage. Both patients complained of painful fetal movements, and real-time ultrasonography demonstrated that the fetus was striking the placental edge.
(Am J Obstet Gynecol 1987;157:830-1.)

Key words: Antepartum hemorrhage, ultrasonography

Trauma has long been known to be a cause of premature placental separation.[1] Such trauma includes blunt injury to the maternal abdomen, external cephalic version, and sudden uterine decompression. As the following two cases illustrate, it would seem that fetal trauma must be added to this list as a cause of antepartum hemorrhage.

Case reports

Case 1. A 24-year-old woman, gravida 4, para 2, came to the labor ward at 36 weeks' gestation as determined by dates and early ultrasound scan with genital tract bleeding. The bleeding had been preceded by painful fetal movements. She had an unremarkable past medical and obstetric history. The results of a cervical smear were negative. An examination showed that the abdomen was soft with a fundal height that was consistent with the dates. The fetus was a transverse lie with the head on the maternal right. An ultrasound scan was performed in the labor ward. The fetal biometry was consistent with the dates, and the estimated weight of the fetus was 3.1 kg. The placenta was noted to be anterior, with the lower edge just reaching the internal os (i.e., a Grade II placenta previa). A loop of cord and both fetal hands were noted to be near the cervix. During the scan, one of the fetus' hands was seen to strike the lower most edge of the placenta and actually indented the lower uterine segment. This occurred several times during the scan, and on each occasion the patient winced with pain and some blood was noted to run from the vagina. The patient was admitted to the hospital and the bleeding subsided spontaneously. At no time was any evidence of uterine contractions detected with external cardiotocography, nor was there any progressive cervical dilatation or evidence of ruptured membranes. The baby was delivered by cesarean section one week later. The patient's postoperative

course was uneventful, and she was discharged with her baby on the seventh postoperative day.

Fig. 1 is a longitudinal scan that shows the fetal hand striking the lower edge of the placenta.

Case 2. A 22-year-old primipara came to the labor ward at 34 weeks' amenorrhea as determined by dates and early ultrasonography. The patient had noticed that fetal movements had become painful, and some minutes later she noticed blood in the vagina. An examination showed that the fundal height was consistent with the dates, and the fetus was a cephalic presentation, right occipitoposterior. A very localized area of tenderness was noted over the right anterolateral portion of the uterus. The cervix was closed, and there was no evidence of leakage of amniotic fluid. External tocography failed to show any uterine activity. An immediate ultrasound scan was performed. The fetal biometry was consistent with the dates, and the estimated weight was 2.5 kg. The placenta was noted to be on the upper right posterolateral wall of the uterus. A small marginal hemorrhage (3.5 by 2.8 cm) was seen over the area of tenderness, clearly stripping up a portion of fetal membranes. Both fetal hands were seen to "punch" this area and caused the patient much pain. The results of a clotting screen were normal. The bleeding subsided spontaneously with no specific treatment, and she was allowed to go home after a few days. The patient returned 1 month later and had a spontaneous normal vaginal delivery.

Fig. 2 shows that the retromembranous clot was in close proximity to the fetal hands.

Comment

Antepartum hemorrhage has traditionally been divided into three types—abruptio placentae, placenta previa, and indeterminate antepartum hemorrhage. This latter group includes marginal hemorrhage from a normally sited placenta.[2] Bleeding from a placenta previa may follow local trauma such as coitus or vaginal examination. Case 1 illustrates that fetal trauma may also cause a low-lying placenta to bleed. Case 2 clearly illustrates that fetal trauma can also sometimes injure the margin of a normally situated placenta.

Both of these cases illustrate the usefulness of ultrasound examination in the accurate diagnosis of the cause of an antepartum hemorrhage. Furthermore, they illustrate the importance of attempting to scan such patients as soon as possible after admission to the hospital. Both patients complained of painful fetal movements followed by vaginal bleeding. The patients' complaint of pain also coincided exactly with the fetus' striking its placenta. In these two cases vaginal bleeding subsided spontaneously without specific treatment. However, had the bleeding not stopped and the fetal movements continued to be painful, it would seem reasonable to sedate the mother and thus sedate the fetus.

A pregnant woman with a high level of naturally occurring immunoglobulin M antibodies to *Toxoplasma gondii*

Eiji Konishi, Ph.D.
Kobe, Japan

A pregnant woman diagnosed as positive for immunoglobulin M antibodies to *Toxoplasma gondii* did not have a subsequent rise of specific immunoglobulin G antibodies until delivery. The antibodies were therefore considered as naturally occurring immunoglobulin M antibodies. The baby was completely normal without any clinical and serologic signs suggestive of congenital toxoplasmosis. (Am J Obstet Gynecol 1987;157:832-3.)

Key words: *Toxoplasma gondii*, pregnancy, natural immunoglobulin M, serodiagnosis

Infection with *Toxoplasma gondii* newly acquired during pregnancy is well known to cause congenital toxoplasmosis in infants. Immunologic diagnosis of toxoplasmosis for pregnant women is therefore in an important position as one of the TORCH (*Toxoplasma*, rubella virus, cytomegalovirus, and herpes simplex virus) group. We report on a case in Japan in which a pregnant woman was erroneously suspected of recent infection with this teratogenic parasite because of a high level of naturally occurring immunoglobulin M antibodies directed against *Toxoplasma*.

Case report

A 31-year-old woman was first examined for pregnancy at a maternity clinic in January 1985. At this time, she presented at 8 weeks' gestation and was found positive for *Toxoplasma* antibodies by a routine latex agglutination test. Although no clinical signs and symptoms were observed in the mother and her fetus, she came to the Department of Gynecology and Obstetrics in our university hospital at 14 weeks and asked for closer examination simply because of fear of the result of the antibody test.

In my laboratory, her serum was initially tested for *Toxoplasma* antibodies by the latex agglutination test, and the titer was 1:256, which is consistent with the previous result. When enzyme-linked immunosorbent assay[1] was used, the serum was only positive for immunoglobulin M class antibodies at an enzyme-linked immunosorbent assay value of 1.046 but was negative for immunoglobulin G antibodies at an enzyme-linked immunosorbent assay value of 0.013. It strongly suggested the recent acquisition of *Toxoplasma* infection accompanied by the risk of fetal infection in her uterus. Fractionation of immunoglobulin G and immunoglobulin M from the serum on sucrose density gradient also resulted in the presence of immunoglobulin M antibodies and absence of immunoglobulin G antibodies. This was further confirmed by the conventional indirect fluorescent antibody test in which the immunoglobulin M antibody titer was found to be 1:80.

At 16 weeks' gestation, the woman was again examined for antibodies. As opposed to the common immunologic knowledge of the course of immunoglobulin G and immunoglobulin M antibodies after infection, the enzyme-linked immunosorbent assay value of immunoglobulin G antibodies was still negligible and that of immunoglobulin M antibodies was still high. A similar situation was again observed at 23 weeks and at delivery. Based on this antibody course, the previous result of latex agglutination test at 8 weeks also seems to be attributed merely to the presence of immunoglobulin M. Serum obtained from the umbilical cord was negative for immunoglobulin M antibodies to *Toxoplasma* at an enzyme-linked immunosorbent assay value of 0.037, and the total amount of immunoglobulin M was less than 20 mg/dl, a borderline value for intrauterine infection. The fetus grew normally during gestation, and the baby subsequently had no clinical signs related to generalized infection, central nervous system abnormalities, or eye lesions, at least during the first 3 months of life.

Comment

The continued high antibody level of immunoglobulin M without a rise in the immunoglobulin G antibody level was unlikely to be explained by a general immune response to the infection. Our recent study on immunoglobulin M antibodies to *Toxoplasma* in a swine population[2] revealed that all persons inherently had a variety of immunoglobulin M antibody levels even without infection, and such antibodies were therefore considered naturally occurring immunoglobulin M antibodies. A survey of a human population negative for immunoglobulin G antibodies also showed the presence of immunoglobulin M antibodies in varying degrees.

If a woman who has a high level of naturally occurring immunoglobulin M antibodies becomes pregnant, she may be probably suspected of recent acquisition of *Toxoplasma* infection, even though neither she nor the baby is infected at least during gestation, as was seen in the present case. The characteristics of naturally occurring immunoglobulin M antibodies compared with immunoglobulin M antibodies raised by infection are now under investigation by means of Western blotting analyses, especially to eliminate such false-positive results for recent *Toxoplasma* infection in pregnant women.

The umbilical cord twist: Origin, direction, and relevance

Ronald V. Lacro, M.D., Kenneth L. Jones, M.D., and Kurt Benirschke, M.D.
San Diego, California

The purpose of this study was to evaluate the origin, direction, and relevance of the umbilical cord twist. We initially hypothesized that the direction of the helix or twist of the human umbilical cord at birth correlated with the eventual handedness of the child. Among 2801 singleton placentas in this study, only 5% had no twist, and the left twist outnumbered the right twist by 7 to 1, a ratio that is strikingly similar to the predominance of right-handed persons to non-right-handed persons in the general population. Forty-five 3- and 4-year-old children with previously documented cord twists were evaluated with respect to hand preference and performance. The direction of the cord twist was independent of the handedness of the child as well as the mother. We have documented an increased incidence of absent twist and right twist in association with single umbilical artery, suggesting that the impetus for the cord twist is independent on hemodynamic forces in the umbilical cord itself. We further document an increased incidence of absent twist among intrauterine fetal deaths and twins, suggesting that decreased fetal movement can impede the forces leading to normal twisting of the umbilical cord. Absence of cord twist may be associated with adverse prognosis. (Am J Obstet Gynecol 1987;157:833-8.)

Key words: Umbilical cord twist, placenta, handedness, asymmetry

The spiral course of the umbilical cord vessels was recorded by Berengarius in 1521.[1] The twist, or more properly the helix of the umbilical cord (Fig. 1), which has been observed as early as 42 days' gestation, is well established by 9 weeks.[2, 3] The number of twists present during the first trimester is roughly the same as that seen in term cords (most often between 0 and 40, but up to 380), indicating that the cord lengthens by an increase in the pitch between each turn of its helix rather than an increase in the number of turns.[1, 4, 5] Although the cause of the twist of the cord is unknown, Leonardo da Vinci observed in the fifteenth century that "the length of the umbilical cord is equal to the length of the child in every stage of its age,"[1] and more recent research suggests that the length of the cord at birth is influenced by intrauterine fetal activity and therefore correlates with fetal well-being. The fact that animals that are normally constrained within an elongated uterine cavity throughout gestation[5] and humans whose intrauterine activity has been abnormally restricted because of intrinsic defects in development or extrinsic constraint[6-10] often have short umbilical cords that lack normal twists suggests that not only the length of the cord at birth but also the twist of the cord depends on intrauterine fetal activity.

In 1600 Fabricius demonstrated with illustrations that both right, or clockwise, and left, or counterclock-

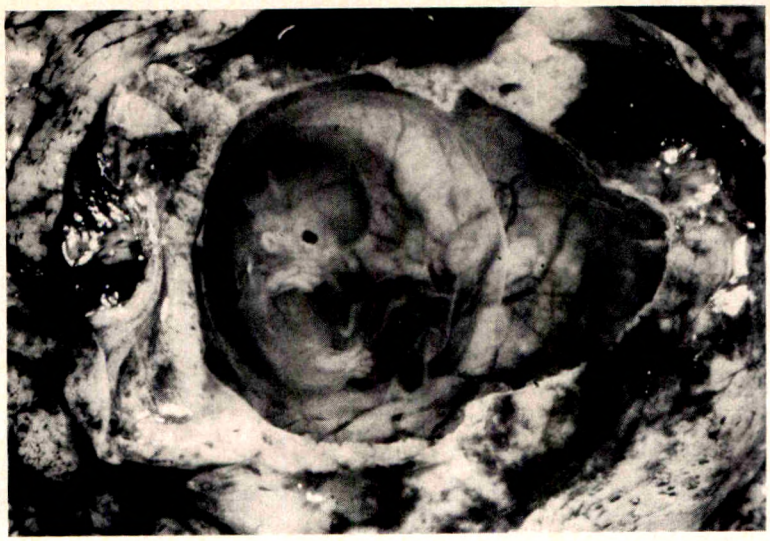

Fig. 1. The umbilical cord twist is well established by 9 weeks' gestation. Note the left twist of the umbilical cord in this 8-week specimen.

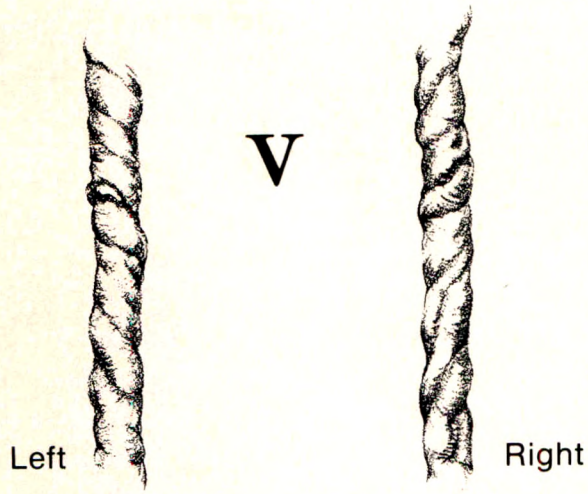

Fig. 2. Direction of the umbilical cord helix: the anterior portion of a left helix parallels the left-hand limb of a letter V, whereas the anterior portion of a right helix parallels the left-hand limb of a letter V.

wise, helices of the umbilical cord occur.[1] If the umbilical cord twist were determined randomly, one would expect the incidence of the right twist to be roughly equal to that of the left twist. However, a long series of investigators have found that the majority of cords twist to the left.[1,3,4] Although the reason for this discrepancy remains unexplained, this disproportion is strikingly similar to the predominance of right-handed persons to non-right-handed persons in the general population.[11] Pande and Singh[12] found significant asymmetry in muscle and bone weight in the upper limbs of human fetuses, the weight being greater on the right side in eight out of nine specimens, suggesting that handedness could conceivably be determined at the time of the umbilical cord twist is being established. The aim of the present study was to determine whether the direction of the cord twist at birth correlated with the eventual handedness of the child and thus reflected the direction that the fetus actively rotated in utero.

Subjects and methods

The placentas of all infants delivered at or transferred to our institution are examined routinely by a single pathologist (K. B.). Microscopic examination and special studies are performed when indicated. Since April 1982 we have recorded the direction of the twist for each umbilical cord. The direction of the helix is established as follows (Fig. 2): If a helix is held vertically the course of the anterior portion of a left helix will parallel the left-hand limb of a letter V, whereas the course of the anterior portion of a right helix will parallel the right-hand limb of the letter V. This will be true no matter in which position the spiral is held. Just as a left-hand screw will be a left-hand screw whether it is driven into a ceiling or a floor, the twist of an umbilical cord is the same whether it is oriented with respect to the fetal or the placental end or whether it is regarded as an independent object.[1]

Placenta records of all infants delivered at our institution in 1985 were reviewed to determine the incidence of left, right, and absent twist of the umbilical cord and the incidence of associated placental abnormalities including immaturity, infarcts, abruptions, meconium staining, circumvallation, succenturiate lobe, congestion, single umbilical artery, cysts, inflammation, and velamentous insertion. There were 2801 live-born singleton placentas with adequate documentation of

cord twist. In addition, we evaluated 71 placentas associated with singleton fetal deaths collected during a 2-year period, 184 placentas associated with live-born and stillborn twins collected during a 4-year period, and 57 placentas associated with live-borns and fetal deaths with single umbilical artery collected during a 4-year period.

Two hundred consecutive placentas and cords with right twists and 200 consecutive placentas and cords with left twists were ascertained from the placenta records of live-born singleton infants born in 1982. These cases were compiled, and the cord twists were concealed. Families were initially interviewed by telephone. A handedness questionnaire[13] was completed for the child and both parents. A medical and developmental history and a complete family history for left-handedness were obtained. Each child was then examined according to an examination protocol designed to evaluate hand preference and performance. The protocol included coloring, figure drawing, eating, clapping, placing marbles into a small hole, and placing key-shaped pegs into a grooved pegboard (Lafayette Instrument Company, Lafayette, Indiana). For some tasks the child was allowed to choose which hand he preferred to use, whereas for other tasks the child was asked to perform the taks with each hand in succession. The interviews and examinations were administered and scored by a single examiner (R. V. L.). The family and examiner were blinded with respect to the umbilical cord twist of the child. The results of the handedness evaluation were confirmed during a follow-up interview 6 to 12 months after the actual examination. Forty-five children, aged 3 to 4 years, were enrolled and completely evaluated with respect to hand preference and performance.

Data were tested for independence by χ^2 analysis. Probabilities of <5% ($p < 0.05$) are reported as statistically significant. To evaluate the effect of fetal death,

twinning, and single umbilical artery on the left/right ratio and incidence of absent twist, we used the 2801 live-born singletons as a control group.

Results

Among live-born singletons, the left twist outnumbered the right twist by 7 to 1 (Table I). Five percent of cords had no twist. The incidence of placental abnormalities was not significantly different between the left, right, and absent twist groups except for congestion and inflammation (Table II).

Among 54 singleton cords with a single umbilical artery, the left-to-right twist ratio was 2.8 to 1 (Table I). The incidence of absent twist (15%) was significantly higher than that for cords with two umbilical arteries ($p < 0.001$). Thirty-seven percent of infants with single umbilical artery were documented to have an associated major structural abnormality, multiple malformation syndrome, or fetal death ("single umbilical artery with problems"; Table I). Although the incidence of absent twist among infants with single umbilical artery with and without problems was significantly higher compared with control subjects, only the infants with problems showed a significant decrease in the left-to-right ratio ($p < 0.001$). There were three sets of twins in which one twin had single umbilical artery. In each set, both cords had left twists.

In only three cases of single umbilical artery were we able to document the side of the absent artery at autopsy. In each of the three cases, the right umbilical artery was either missing or extremely hypoplastic. Two subjects with completely absent right artery had right twists. The one patient with extremely hypoplastic right artery had a left twist.

Among 184 twin pairs (Table III), 120 (65%) were concordant for left twist, only seven (4%) were concordant for right twist, and 35 (19%) showed one left and one right twist. The remainder (22 twin pairs, 12%) showed no twist in one or both twins ($p < 0.001$). When each member of a twin pair was treated as an individual, left twists outnumbered right twists by 7.8 to 1 for monochorionic twins and by 4.8 to 1 for dichorionic twins. The number of individual twins with no twist was 7% for monochorionic and 8% for dichorionic twins (Table I).

Among 71 cords associated with singleton fetal deaths (Table I), 73% had left twists, 8% had a right twist, and 18% had no twist ($p < 0.001$ for absent twist).

Of the 45 children evaluated for handedness (Table IV), 23 were from the left twist group and 22 were from the right twist group. There were no major medical or developmental problems with either group. There were no significant differences in frequency of first-, second-, or third-degree relatives who were left-handed. The number of non-right-handed children (20%) is consistent with previously reported estimates for the general population.[11] There were only four mothers who were left-handed, indicating that the twist is independent of the handedness of the mother. Furthermore, the prevalence of right- versus non-right-handed mothers was not significantly different between the two groups. Among the 23 children in the left twist group, 17 (74%) were right-handed and six (26%) were non-right-handed (five left-handed and one mixed-handed). Among the 22 children in the right twist group, 19 (86%) were right-handed and three (14%) were non-right-handed (one left-handed and two mixed-handed).

Comment

A variety of theories have been proposed to explain the umbilical cord twist, most of which fall into two general groups: those that interpret the twist as inherent to the cord itself and those that explain the twist as the effect of active or passive rotation of the fetus.[1] The data set forth in this report suggest that both factors are relevant: that the impetus for cord twisting is inherent to the umbilical cord itself and that the normal twist can be impeded by any factor that restricts normal fetal movement. Supporting evidence documented in this study as well as from the literature is as follows.

Malpas and Symonds[4] described an experimental model that provided evidence that the umbilical cord twist is a property intrinsic to the cord itself. Hollow tubes whose walls were constructed from fibers with inbuilt torsion were shown under hydrostatic pressure to exhibit the typical helical shape of the cord. The direction of the twist of the tube was contrary to the direction of the twist of the fibers constituting its walls. They postulated that the helical configuration protected blood flow because it enabled the cord to withstand torsion without snarling.

Several authors have previously proposed theories that stress the importance of asymmetry in size of the umbilical arteries. Grosser explained the twist as the result of unequal growth of the umbilical arteries, whereas Simpson held that a rotational torque resulting from differential blood flow between the left and right umbilical arteries could produce the twist in the umbilical cord.[1] The fact that the right umbilical artery is usually larger than the left umbilical artery would explain why the left twist is more common than the right twist. In fact, among live-born singletons in this study the left twist outnumbered the right twist by 7 to 1. Previous authors have reported left/right ratios ranging from 1.1 to 7.0[1, 3, 4]; however, the largest study to date included only 707 umbilical cords compared with the 2801 cords in the present study (Table V).

Among 54 cords with a single umbilical artery in this study, the incidence of absent twist was significantly increased among infants with single umbilical artery. If the origin of the twist is dependent on the torque resulting from differential blood flow between the two umbilical arteries, then in the presence of a single umbilical artery the incidence of absent twist would be expected to increase. Two further features noted among cords with single umbilical artery are relevant with respect to the theory that the impetus for the cord twist comes from within the cord itself and is dependent on the dynamic forces arising from differential blood flow: (1) the left-to-right twist ratio decreased to 2.8, largely as a result of the random distribution of left and right twists in the infants with single umbilical artery with problems (left-to-right ratio of 1.1) and (2) in the two cases of completely absent right umbilical artery, the cord twist was to the right.

The cause and time of onset of the single umbilical artery probably are different for infants with isolated single umbilical artery as compared with infants with malformation syndromes in which single umbilical artery is one feature. In the latter group the missing umbilical artery most likely represents a primary defect in embryologic development and is present before the initiation of the cord twist and therefore can affect its direction. Assuming a random loss of either the right or left umbilical artery, the direction of the cord twist would be expected to relate to the remaining or dominant artery. In the two cases of completely absent right umbilical artery documented in this study, as one would expect, there was a right cord twist conforming to the rotational torque imposed on the cord by blood flowing through the remaining left umbilical artery. The single umbilical artery in otherwise normal infants most likely develops after 42 days' gestation secondary to atrophy

of one umbilical artery, is not present until after the cord twist is established, and thus has no influence on its direction.

Previous reports have documented short umbilical cords that lack a twist in both humans and animals in which fetal activity has been restricted, suggesting that the cord twist also can be affected by active or passive rotation of the fetus.[5-10]

A particularly popular theory referred to here as the "bathtub vortex theory" has suggested that the fetus in utero rotates in a counterclockwise direction in the northern hemisphere and in a clockwise direction in the southern hemisphere similar to the direction of rotation of a hurricane or water draining out of a bathtub.[14] However, of 36 placentas examined in Australia, 24 had a left cord twist, eight had a right twist, and four were indeterminate, tending to discount the possible influence of the bathtub vortex on the cord twist phenomenon (Short RV, Brennecke S, personal communication, 1986).

Careful evaluation of hand preference and performance of a group of 3- and 4-year-old children ascertained by their cord twist indicates that the handedness of neither the child nor the mother correlates with the direction of the twist of the umbilical cord. Although these data discount the initial hypothesis set forth in this article that the predominance of left twists is the result of more forceful paddling with the right arm of a fetus who has already established handedness, it does not negate the theory set forth by a number of investigators that the cord twist is the result of either active or passive rotation of the fetus.[1] Documentation in this study of an increased incidence of absent twists among twins gives credence to the theory that fetal rotation is necessary for the normal umbilical cord twist to occur. By virtue of intrauterine crowding, twins have an increased incidence of constraint-related defects including short umbilical cords.[15] It is therefore not surprising that rotation of the fetus to either the left or right would occur less frequently in twins than in singletons. Furthermore, documentation of an increased incidence of absent twists among spontaneous abortuses and stillbirths suggests that decreased fetal activity as a result of fetal defects can also adversely affect cord twisting. Thus, decreased fetal activity as a result of intrinsic (fetal) and extrinsic (intrauterine constraint) causes can affect the cord twist phenomenon.

Although the data set forth in this article indicate that the origin of the umbilical cord twist reflects the rotational forces within the cord itself caused by differential blood flow between the two umbilical arteries, these data also indicate that decreased fetal activity plays a role in impeding normal cord twisting. That the umbilical cord most frequently rotates to the left as a result of asymmetric blood flow between the right and left umbilical arteries is further indication of the developing organism's propensity for asymmetric development.[11] Just as a short umbilical cord has been associated with an increased incidence of neurologic problems and developmental delay, absence of a cord twist may be associated with adverse developmental prognosis.

We are grateful to the children and families who participated in the handedness study, Jyotsna Vaid, Ph.D., for her assistance in developing the handedness evaluations, Alex Tawse and Christina Henrikson for their help in placental data collection, G. Paul Shragg for the statistical analyses, and Cindy Fujii, M.D., for reviewing the manuscript.

Indicators of perinatal asphyxia

David I. Hollander, M.D., Linda Wright, M.D., David A. Nagey, M.D., Ph.D., John N. Wright, Ph.D., Marcos J. Pupkin, M.D., and Thomas Koch, Ph.D.

Baltimore, Maryland

Creatinine phosphokinase and its isoenzymes (myocardial-specific MB and brain-specific BB) are elevated in the presence of specific tissue injury. The value of this serum marker as an objective indicator of perinatal asphyxia was studied. Forty-nine patients with gestational ages ranging from 36 to 42 weeks were prospectively studied. Patients who by interpretation of the fetal heart rate tracing alone were diagnosed as having fetal distress demonstrated significantly lower pH ($p = 0.001$) and base excess ($p < 0.0001$) in umbilical venous blood. Umbilical venous cord MB ($p < 0.05$) and BB ($p < 0.01$) were increased in this group. Abnormal fetal heart rate patterns correlate well with acid-base abnormalities and elevated creatinine phosphokinase values. These tests may demonstrate more efficient and improved indicators of tissue injury and damage from perinatal asphyxia than clinical observation alone. (Am J Obstet Gynecol 1987;157:839-43.)

Key words: Asphyxia, creatinine phosphokinase, acid-base balance

Intrapartum asphyxia has long been recognized as a major contributor to neonatal morbidity, mortality, and long-term sequelae.[1] It has been singled out by some authors as the leading cause of neurologic morbidity in term infants as well as significantly influencing the morbidity in the preterm neonate.[2] Despite the magnitude of its importance, the accurate and objective diagnosis of this disorder remains elusive.

Apgar scoring,[3] which was developed to quantitate the initial evaluation of the newborn infant and direct medical attention to infants in need of immediate resuscitation, has been the most widely used index of asphyxial assessment at birth. However, Apgar scores are not specific for hypoxia, and they do not appear to closely correlate with intrapartum indicators of asphyxia.[4]

Acid-base analysis of umbilical cord blood provides objective information on the acute and chronic respiratory and metabolic condition of the fetus at birth. Although it appears that this analysis may provide specific criteria for evaluation of the condition of the fetus at birth, its validity has been tested only against Apgar scoring.[4, 5] Similarly, its value as a true predictor of the condition of the fetus is best judged when maternal acid-base analysis is normal, since maternal respiratory and metabolic derangements may falsely increase or decrease the fetal pH value.

Therefore there is no ideal measure of perinatal asphyxia in clinical practice. Apgar score, fetal heart rate monitoring, and umbilical cord blood gas analysis have been shown to not correlate well with asphyxia.[1-6] More specific and objective criteria need to be developed and tested.

Creatinine phosphokinase and its isoenzymes, BB or brain-specific fraction (CPK_1), MB or myocardial-specific fraction (CPK_2), and the muscle-specific fraction MM (CPK_3) are known to elevate in response to muscle trauma, myopathy, severe exertion, or muscle hypoxia. Therefore the use of this marker as a detector of tissue-specific damage in response to intrapartum fetal distress is quite intriguing.

Material and methods

Forty-nine patients who came to the University of Maryland Hospital between Oct. 1, 1984 and May 31, 1985 were studied. Eligibility was based on a gestational age of 36 weeks or greater, electronic fetal heart rate monitoring for a minimum of 30 minutes, and written informed consent. No other factors that would potentially affect the values of our creatinine phosphokinase levels such as Duchenne-Landouzy dystrophy, tetany, fenoterol, hypothyroidism, or extreme trauma were present for study inclusion. At the time of delivery, the umbilical cord was doubly clamped and divided. Samples of umbilical arterial and venous blood were drawn into heparinized syringes and analyzed by a Corning 170 blood gas analyzer with base excess calculated by the Siggard-Anderson[7] nomogram. Umbilical arterial values were used for statistical analysis of blood gas results.

Table I. Categoric definitions of patients

Group	*Interpretation*	*Definition*
I (n = 20)	Normal	No fetal heart rate abnormalities
II (n = 9)	Mild distress	Fetal heart rate change noted; no intervention recommended
III (n = 20)	Moderate to severe	Fetal heart rate change severe enough to mandate treatment—scalp pH or delivery

Umbilical venous cord blood was simultaneously obtained at the time of delivery from the same doubly clamped cord specimen for evaluation of creatinine phosphokinase isoenzymes. A second venous serum sample was drawn from the neonate at 30 hours of age (±6 hours) for isoenzyme activity of creatinine phosphokinase. Immediately after the specimens were drawn, the samples were transported on ice to the laboratory where analysis was performed with the Beckman Paragon creatinine kinase isoenzyme electrophoresis kit (Beckman Instruments, Inc., Palo Alto, Calif.). The principles of this procedure are based on creatinine phosphokinase catalyzing the reversible transer of a phosphate group from creatinine phosphate to adenosine diphosphate forming adenosine triphosphate. The rate of adenosine triphosphate formation is measured through the use of the two coupled reactions catalyzed by hexokinase and glucose 6-phosphate dehydrogenase. The rate of reduction of nicotinamide adenine dinucleotide to nicotinamide adenine dehydrogenase is followed by measuring the increase in absorbance at 340 nm. The rate of change in absorbance is directly related to the activity of creatinine phosphokinase in the specimen.[8] Electrophoretic separation of the isoenzymes of creatinine phosphokinase may then be quantitatively analyzed when subjected to densitometric scan, and the relative amounts of the different isoenzymes are calculated as percentages and then finally recorded as international units per liter of creatinine phosphokinase activity.

Analysis of fetal heart rate tracings was performed by a perinatologist who was unaware of the patients' identity and eventual outcome. The categoric division of patients by this method is demonstrated in Table I. Neonatal evaluation was made up of Apgar scoring at 1 and 5 minutes by the obstetric and pediatric staff and confirmation of gestational age was by Dubowitz examination. Results were analyzed with the Spearman rank correlation coefficient and Mann-Whitney U test where appropriate. Nonparametric techniques were used despite the probability of a decrease in power since our data did not appear to be distributed normally.

Results

Table II summarizes the correlation between cord blood gas analysis and creatinine phosphokinase isoenzymes at the two sampling points. As predicted, cord pH was correlated with base excess. The myocardial-specific isoenzyme of creatinine phosphokinase (CPK_2) at birth was significantly correlated with the base excess of the umbilical cord ($r = 0.36$, $p < 0.005$). At 30 hours, both the heart-specific fraction (CPK_2) and the brain-specific isoenzyme of creatinine phosphokinase (CPK_1) were significantly correlated with the degrees of base excess present in umbilical cord blood samples. Although there was not a significant correlation between cord pH and isoenzyme fractions of creatinine phosphokinase at either time point, there tended to be a higher correlation between isoenzyme levels and base excess levels from the umbilical cord than with cord pH at both sampling times.

Division of patients on the basis of interpretation of fetal heart rate (Table III) was then performed, and the differences between groups were analyzed. There were significant differences between infants with normal fetal heart rate tracings as opposed to those demonstrating electronic evidence of moderate to severe fetal distress in umbilical cord pH ($p = 0.001$) and base deficit ($p < 0.0001$). The BB (CPK_1) isoenzyme level in group III (moderate severe distress) infants was significantly greater ($p < 0.01$) at birth than the corresponding level in infants with normal fetal heart rate tracings (group I). Although the second sample taken at 30 hours of age demonstrated that the BB (CPK_1) isoenzyme level of infants with moderate to severe fetal heart rate abnormalities was higher than in those with normal heart rate tracings, it failed to reach statistical significance. Examination of the MB (CPK_2) fraction revealed similar findings, with the isoenzyme at birth being significantly greater ($p < 0.05$) in group III infants while those samples drawn at 30 hours of age, although seemingly higher, failed to demonstrate statistical significance in comparison with the normal group.

The population was divided into two groups: group A, cord pH of ≤7.25 versus group B, cord pH of >7.25. This value was chosen, since it represents a period of preacidosis whereby plans for potential intervention in the birth process should be begun.[9] This separation demonstrated that the MB isoenzyme of the umbilical cord was significantly elevated ($p < 0.05$) in group A versus group B (Table IV). The MB fraction from the neonate at 30 hours of age, however, was not found to be significantly different in the two groups despite the increased acidosis present at birth in group A. The BB isoenzyme of creatinine phosphokinase was

unable to differentiate the groups at either sampling time periods. Identical results were obtained when the division was based on base excess (group A = base excess ≤ -10) (group B = base excess > -10).

Comment

The present study demonstrates strong support that creatinine phosphokinase and its isoenzymes are elevated when there is fetal distress as judged by electronic monitoring of fetal heart rate. These increases are presumed to occur as a result of ischemia-induced leakage of enzymes from damaged cells in tissue in which the isoenzymes are concentrated. In conjunction with this rise in enzyme activity is a lowering of cord pH values and an increase in base deficit, which probably indicate that hypoxic damage has occurred.

Examination of the population as a whole demonstrated a significant correlation between the degree of base excess and creatinine phosphokinase activity (Table II). This same association, however, is not found in conjunction with pH values. Hypoxia and/or asphyxia result in diminution of oxygen tension and an increase in carbon dioxide tension levels. In time this leads to anaerobic metabolism and lactic acidosis. Acid-base status may change rapidly in response to the changes in P_{CO_2} values, but base excess reflects a damped or conservative picture of the magnitude of the metabolic changes from normal, changing only after prolonged hypercarbia. In a similar manner, the myocardial-specific isoenzyme (CPK_2), with its longer half-life (peak rise 24 hours after injury), would appear more pivotal as an assessment of asphyxial insults than

its shorter-lived counterpart, the brain-specific isoenzyme (CPK_1) (peak rise 6 hours after injury). This is in fact our observation. Therefore explanation of the correlation of CPK_1 at 30 ± 6 hours of age with base excess leads to the hypothesis that this enzyme increase is not a primary response to the birth process but perhaps a secondary response to some degree of myocardial injury that has occurred during or after labor and delivery.

In 1966 Rudolph and Gross[10] first reported creatinine phosphokinase values at 24 hours of age in infants delivered by emergency cesarean section, which followed prolonged labors and oxytocin infusion and after delivery from breech presentations. They suggested that muscle trauma was the likely cause for these increases. In 1978 Becker and Menzel,[11] who examined the value of the brain-specific creatinine kinase enzyme in the serum of newborn infants with perinatal damage, demonstrated a pattern of neuropathologic symptoms, an increase in total activity of serum creatinine kinase, and an increase in the brain-specific isoenzyme when there is central nervous system damage and an unfavorable prognosis. Warburton et al.[12] suggested that elevated levels of creatinine phosphokinase reflected perinatal asphyxia. Their data demonstrated a correlation between acidosis, 1-minute Apgar scores, and isoenzyme levels of creatinine phosphokinase in the neonate infant. These data, however, are only based on neonatal data collection without reference to intrapartum events or differentiation between the acute and chronic respiratory and metabolic condition of the neonate.

Subsequent research has been unable to clarify clearly the relationship between abnormal fetal heart rate patterns, asphyxia, and isoenzyme elevations of creatinine phosphokinase in the newborn. In 1985 Feldman et al.[13] demonstrated a direct association between ominous fetal heart rate patterns and cord BB, although there was no significant elevation of the creatinine phosphokinase myocardial fraction. In contrast, Woolley et al.[14] reported increases in MB activity at 36 ± 6 hours of age, although not at birth in neonates with abnormal fetal heart rate tracings. Neither study investigated the relationship between the metabolic status of the infant at birth and creatinine phosphokinase levels.

The diagnosis of fetal distress by electronic fetal heart rate tracings is known to be fraught with many false-positive interpretations.[15] The classification of these recordings by the simplified system we used is less than ideal. Scoring indexes have been developed and may be more specific as diagnostic tools.[16] The timing of when changes in the fetal heart rate pattern began and their duration may have aided the mapping of enzyme rises. Stress precedes distress, and it is known that a considerable time delay occurs before biochemical parameters fall outside the physiologic normal range. However, our data, as well as previous investigations by others, demonstrate that tissue injury appears to occur when fetal heart rate patterns are abnormal. The paucity of neonatal follow-up in our study prohibits the accurate assessment of the clinical significance of this finding. These deficiencies are currently being corrected.

The value of creatinine phosphokinase and its isoenzymes as a way to identify the severity of fetal distress at this time is limited. Wide fluctuations in the isoenzyme results obtained would lead to considerable confusion in the diagnosis of distress with the means currently available. The potential validity of creatinine phosphokinase isoenzymes as markers of fetal/neonatal asphyxia must not be overlooked. The significant correlation that CPK_1 and CPK_2 demonstrate with respect to the acid-base status of umbilical cord sera and their concomitant relationship with abnormalities in fetal heart rate lend support to the possibility that these markers may play a role as predictors of fetal hypoxia. Equally intriguing is the failure of these parameters to correlate with the present gold standard to many in clinical practice today, Apgar scores. Results of ongoing analyses of changes in fetal heart rate responses to labor with respect to time in relation to cord blood determination of creatinine phosphokinase may shed light on whether isoenzyme analysis will succeed other techniques as markers of perinatal hypoxia.

In addition, it would seem prudent to attempt to establish specific and objective criteria for the evaluation of fetal outcome other than Apgar scores. One must remember that the identification of asphyxia is based on hypoxia, hypercarbia, and acidosis. In turn perinatal asphyxia may then lead to tissue damage of the heart and brain. The role that creatinine phosphokinase isoenzyme levels and umbilical cord acid-base studies may play needs delineation. Prospective evaluation of these parameters with respect to specific fetal heart rate changes, their timing and duration, and fetal outcome through more vigilant study of the neonatal course, neurologic performance, and myocardial status of the newborn is needed. This knowledge will hopefully lead to more efficient indicators of tissue injury and the presence or absence of asphyxial changes. Perhaps armed with this knowledge, we will be better prepared to monitor improvements in antenatal and intrapartum care.

Umbilical cord blood pH and Apgar scores as an index of neonatal health

Bruce E. Josten, Captain, USAF, MC, Timothy R. B. Johnson, Major, USAF, MC, and John P. Nelson, Major, USAF, BSC

Andrews Air Force Base, Maryland

In an effort to determine the clinical usefulness of Apgar scoring and cord pH in neonatal management, specimens of umbilical cord blood were obtained after 257 of 329 consecutive deliveries at a community-based hospital. A notable number of babies who were born in a vigorous state were in fact acidotic (umbilical arterial pH >1 SD below mean). Seventy-two percent of acidotic babies had an Apgar score >7 at 1 minute, and 92% had an Apgar score >7 at 5 minutes. Correlation coefficients of Apgar scores at 1 and 5 minutes and arterial pH with the health status of newborn infants were poor. A χ^2 analysis of arterial pH and Apgar scores at 1 and 5 minutes indicated that a larger number of sick babies had an Apgar score <7 and acidosis than expected by pure chance. However, the sensitivity values of the Apgar score at 1 minute (0.48) and 5 minutes (0.24) and the arterial pH (0.40) for predicting sick children limit the clinical usefulness of these tests. While technically feasible in a community hospital, routine cord pH measurements add little to neonatal evaluation and management. (AM J OBSTET GYNECOL 1987;157:843-8.)

Key words: Acidosis, arterial pH, Apgar score

Rapid neonatal assessment of intrapartum and delivery acidosis and asphyxia as an index for various neonatal risks was the intent of Virginia Apgar when she introduced her system in 1953. This was also the purpose of her research in the ensuing years.[1] However, the application of this system is limited today because of improved newborn resuscitation and neonatal care, which have resulted in improved Apgar scores at 5 minutes.

Many contend that neurological abnormalities of the infant are a result of oxygen deprivation before delivery and are infrequently compounded by asphyxia of the newborn infant itself. It is difficult to determine whether poor Apgar scores are the result of oxygen deprivation before delivery or expressions of already abnormal babies. Therefore the long-term predictive value of the Apgar system is questionable. In fact, large collaborative studies completed in the late 1960s[2] in-

Arterial pH	0.2454 257	0.3454 257	0.1885 257	1.0000 257
Venous pH	0.2230 273	0.3087 273	0.1919 273	0.7936 273

The top number is the correlation coefficient. The bottom number is the total number of cases.

dicated that >80% of children with 5-minute Apgar scores <7 did not have abnormal neurological findings at 1 year of age. More recent data indicate that Apgar scores are only minimally related to neurological outcome in either the short or long term.[3-9]

The Apgar system often seems to be subjective in its applications, and it has shortcomings. Numbers are often assigned in retrospect. Scores are often inflated secondary to provider inexperience, ego, or fear of criticism by management. The timing of Apgar score assignment is not always coincidental with 1 and 5 minutes after birth. Umbilical artery data at delivery should correlate more closely with the metabolic status of the fetus just before birth than subjective Apgar scoring.

Sykes et al.[10] evaluated large numbers of umbilical arterial cord blood samples as an objective assessment of intrapartum and delivery acidosis. Of their babies with a 1-minute Apgar score <7, only 21% were acidotic, and only 19% of those with an Apgar score at 5 minutes <7 were acidotic. Of the babies with arterial cord blood pH <1 SD below the mean, 73% had an Apgar score at 1 minute >7 and 86% had an Apgar score at 5 minutes >7. These results indicate that Apgar scores are poor predictive indicators of fetal acidosis. A recent study by Silverman et al.[11] of 1032 neonates also indicated that, except in the case of severe blood gas abnormalities, umbilical artery metabolic status is not closely related to Apgar score. All blood gas parameters—including pH—failed to predict which infants were depressed according to the Apgar score.

Our prospective study was undertaken in an attempt to correlate Apgar scoring with newborn acid-base status in a smaller and less high-risk population hospital setting than that used in previous research.[10, 11] Most important, the early neonatal course was followed up to determine the clinical usefulness of Apgar scoring, cord blood pH testing, and the combination of the two modalities in neonatal management.

Material and methods

Venous and arterial cord blood samples were drawn from a segment of triple-clamped cord. The cord was clamped immediately after delivery, and blood sampling was completed as soon after delivery as possible. Lievaart and deJong[12] have shown that cord clamping is necessary to keep umbilical cord blood pH, carbon dioxide partial pressure, and base deficit values close to time zero results. Samples were obtained in consecutive deliveries without regard to maternal or fetal condition, course of labor and delivery, or establishment of respirations.

Each specimen was drawn into a standard arterial blood gas syringe that had been preheparinized with 1 ml of 1000 U/ml of heparin solution. Arterial and venous punctures were completed with a 20-gauge needle.[13] Residual air was ejected, the syringe was capped with a provided plastic cover, the specimen was placed on ice, and blood gas determinations were completed as soon as possible (preferably within 60 minutes). Strickland et al.[14] have shown that there is minimal change in arterial blood pH values if analysis is completed in <120 minutes. Other researchers have shown that icing cord blood samples does not change the rate of arterial pH decrease.[15] The cord blood gas analysis was completed on an Instrumentation Laboratories Model 1303 analyzer with documented accuracy and daily calibration.

Data collected for each patient included hospital number, date and time of delivery, Dubowitz (gestational age) score, Apgar scores at 1 and 5 minutes, birth weight in grams, race, arterial and venous cord blood gas study results, and time of blood gas analysis completion. The neonatal course of each baby was also recorded. Nursery personnel were not informed of any blood gas study results, in an effort to limit bias in their management. Consistency of diagnosis and management was assumed by a single neonatologist attending physician during the study period. Acidosis was operationally defined as arterial pH at least 1 SD below the mean. Abnormal Apgar scores were defined as <7 at 1 and 5 minutes. Newborn infants placed in the neonatal intensive care unit for observation and treatment because of clinical illness (excluding hypoglycemia and hyperbilirubinemia) were classified as "sick." These babies were those with meconium aspiration (two), subarachnoid hemorrhage (one), pneumothorax (one), polycythemia (one), respiratory distress syndrome (two), transient tachypnea (three), and radiographic evidence of pulmonary disease requiring oxygen support (seven) and those receiving antibiotics for signs of sepsis (eight). A relationship between these illnesses and prenatal and perinatal events has been widely accepted.

Table II. Comparison of the Apgar score at 1 minute and arterial pH

	Apgar score at 1 min				
	<7		>7

$\chi^2 = 27.205$; df = 1; $p < 0.00001$.
*Arterial pH ≥ 1 SD below mean indicates acidosis.

Results

Data were analyzed in two stages. First, to rule out selection bias, an in-depth analysis was performed to verify that the cases for which pH data were not obtained were not significantly different from the study population. Second, the major question of this study, the clinical usefulness of Apgar scoring and cord blood pH testing in neonatal management, was addressed.

Specimens of cord blood were drawn after 257 of 329 consecutive deliveries over a 14-week period in a level 2 community-based hospital. Only those cases with arterial and venous control values were included in the study. Of the 257 deliveries for which both arterial and venous data were available, 224 (87%) were vaginal deliveries and 33 (13%) were cesarean deliveries. Blood pH data were not obtained in 72 deliveries (21.9%) because of inadequate sampling (16 cases with venous pH data only), inadequate manpower, or technical difficulties with cesarean deliveries completed in the operating room. The problem with the operating room accounted for a significantly larger number of cesarean deliveries being missed (37.5%) as compared with vaginal deliveries (19.7%). Thirty-four children were labeled as sick with clinical illness and received treatment consisting of oxygen support or antibiotics. Blood pH data were missing for only 21.4% of babies labeled as being well and for 26.5% of babies labeled as sick. This was not statistically significant. In agreement with previous research,[16] a high correlation was noted between arterial pH and venous pH values (r = 0.7936); therefore we elected to use arterial pH values as the basis for our analysis. Because combining other blood gas data (bicarbonate deficit or partial pressures of carbon dioxide or oxygen) with pH has been shown to add only a slight advantage in the prediction of infants with low Apgar scores,[11] and because our data were consistent with this, we report pH values alone for simplicity and practicality.

Mean time from delivery to blood gas analysis was 71 minutes. There was no correlation between the interval from delivery to blood gas analysis and arterial pH.

The race distribution was 64.6% white, 30.7% black, and 4.7% other (Oriental, Hispanic, and mixed). There was no significant difference in the percentage of white (19.8%), black (24.8%), and other (23.5%) babies missed for all deliveries.

Multiple *t* test analyses were completed to determine if there were differences between cases with and cases without arterial pH data. There were no significant differences, suggesting that the two populations are essentially equivalent across the variables critical to this study and that no selection bias existed for those cases without arterial pH gas data (data available on request).

The mean arterial pH of all 257 cases was 7.2171 (SD = 0.0756). The mean arterial pH of sick babies was 7.161 (SD = 0.1127), and that of well babies was 7.2232 (SD = 0.0681). The difference between the

	39		218		257

$\chi^2 = 11.209$; df = 1; $p < 0.0008$. Sensitivity = 0.40. Specificity = 0.875.

Table V. Comparison of Apgar score at 1 minute and health status

	Apgar score at 1 min				
	<7		*>7*		
	n	*%*	*n*	*%*	*No.*
Sick	12	48	13	52	25
Well	9	4	223	96	232
	21		236		257

$\chi^2 = 56.114$; df = 1; $p < 0.00001$. Sensitivity = 0.48. Specificity = 0.96.

Table VI. Comparison of Apgar score at 5 minutes and health status

	Apgar score at 5 min				
	<7		*>7*		
	n	*%*	*n*	*%*	*No.*
Sick	6	24	19	76	25
Well	0	0	232	100	232
	6		251		257

$\chi^2 = 46.971$; df = 1; $p < 0.00001$. Sensitivity = 0.24. Specificity = 1.00.

mean pH values of sick and well babies was statistically significant ($t = 4.012$; df = 255, $p < 0.0001$).

Pearson's r product-moment correlation coefficients of the total population of deliveries for health (sick versus well), arterial pH, Apgar score at 1 minute, and Apgar score at 5 minutes were low, the best being the Apgar score at 1 minute (Table I).

Cross-tabulation analysis of Apgar scores at 1 and 5 minutes versus acidosis (arterial pH >1 SD below the mean) is noted in Tables II and III. The χ^2 analysis for the Apgar score at 1 minute ($X^2 = 21.5459$; df = 1) and at 5 minutes ($X^2 = 27.205$, df = 1) was significant.

Only 52.3% of the babies with an Apgar score at 1 minute <7 and 50% of the babies with an Apgar score at 5 minutes <7 were acidotic. Seventy-two percent of the babies with acidosis had an Apgar score ≥7 at 1 minute, and 92% had an Apgar score ≥7 at 5 minutes.

Analysis of arterial pH, Apgar score at 1 minute, and Apgar score at 5 minutes versus health (sick versus well) were completed. The χ^2 values indicate that the number of sick babies who were also empirically ill, as determined by acidosis (Table IV) or Apgar scores at 1 minute <7 (Table V) or 5 minutes <7 (Table VI) were significantly greater than expected by chance. As was anticipated, all six babies with an Apgar score at 5 minutes <7 were sick. However, the sensitivity value of this measurement for predicting sick children was poor (0.24), as 76% of babies of who were sick had an Apgar score at 5 minutes >7 (Table VII). This was probably related to proper newborn resuscitation measures that might have significantly contributed to outcome. The arterial pH and Apgar score at 1 minute <7 sensitivity values for predicting sick children were also poor. The best was the Apgar score at 1 minute <7 (0.48) (Tables IV and V).

Because acidosis and the Apgar scores at 1 and 5 minutes were not as individual measures sensitive

indicators of health status, composite measures of arterial pH and Apgar scores versus health (sick versus well) were developed (Tables VII and VIII). Again, the χ^2 values are statistically significant; however, even the combination of acidosis or Apgar score at 1 minute <7 produced a sensitivity level of only 0.60.

Comment

It is generally accepted that severe metabolic acidosis is related to highest fetal risk. Apgar scores may not be very good estimates of this risk and are subjective. Umbilical pH determinations may better serve this purpose.

We have shown that accurate cord blood gas analysis can be accomplished in an average-size community hospital (250 beds) with the use of routine blood gas sampling and analysis equipment. An in-depth analysis of population equivalence between cases with and without arterial pH data identified no significant differences between the two. This indicated that cases missed because of technical problems were due to chance, and that selection bias was not present. This population is different than those previously studied because most patients had relatively uncomplicated conditions. There were few preterm infants; most were term and appropriate for gestational age.

In an effort to be consistent with Sykes et al.,[10] we considered an arterial pH >1 SD below the mean (pH <7.14) to be indicative of fetal acidosis. We are in agreement that a high proportion of vigorous babies can be born with severe acidosis (Tables III and V). Also, the correlations between pH, Apgar score at 1 minute, and Apgar score at 5 minutes were poor (Table II). The real dilemma however, is how these and other results[7-11] applies to clinical practice. In our study the usefulness of cord arterial pH and Apgar score values in predicting which babies would be clinically ill during their neonatal hospital course was examined closely. Although the difference between mean arterial pH values for the babies who were sick versus those who were well is statistically significant, the correlations of arterial pH, Apgar score at 1 minute, and Apgar score at 5 minutes to health status (sick versus well) are certainly not impressive. In fact, Apgar scores (especially the Apgar score at 1 minute) correlated better than blood pH values with health status (Table I).

Cross-tabulation analyses of arterial pH, Apgar score at 1 minute, and Apgar score at 5 minutes versus sick and well babies yielded statistically significant differences between the sick and well subpopulations. However, in light of very poor sensitivity levels, these statistical differences may not be useful for routine clinical decisionmaking. In fact, 60% of sick babies were predicted to be well by arterial pH criteria and 52% by Apgar score at 1 minute criteria (Tables IV and V). To obtain a clinically useful test, two composites of Apgar score at 1 minute and/or arterial pH versus health (sick versus well) were tabulated (Tables VII and VIII). The best composite, Apgar score at 1 minute or arterial pH, was only 60% sensitive for sick babies; therefore 40% of sick babies were predicted to be well.

Because the study sample was a low-risk obstetric population from a community-type hospital, more stringent criteria such as a pH 2 SD below the mean (≤7.1) or Apgar scores at 10 or 20 minutes might have been more predictive, as suggested by others.[4,5] On the

other hand, our data support a growing body of information that intrapartum events are less predictive than have been previously believed.[8, 9]

Umbilical cord blood analysis is very easy to perform and is an objective estimate of fetal biochemistry. The percentage of babies born with severe acidosis in a vigorous state is certainly greater than most clinicians would predict. It is reasonable to consider that severe metabolic acidosis in the fetus reflects oxygen deprivation and the likelihood of asphyxial brain damage. Assessment of the predictive value of cord blood results and neurological damage is beyond the scope of this study. The clinical utility of completing cord blood analyses will depend on additional research with long-term neurological and developmental assessment of acidotic and normal children. However, we can safely state that routine umbilical cord blood pH analysis is not clinically helpful in early neonatal evaluation and management.

A special thanks to all technicians and nurses at Malcolm Grow United States Air Force Medical Center, especially Captain K. Anderson, without whose help this study could not have been completed.

Cervical endometriosis: Facilitated diagnosis by fine needle aspiration cytologic testing

Maria M. Veiga-Ferreira, M.D., Gladwyn Leiman, M.B., B.Ch., Fiona Dunbar, M.B., B.Ch., and Karin A. Margolius, F.C.Path.(S.A.)

Johannesburg, South Africa

Regarded as infrequent, endometriosis of the cervix probably occurs more commonly than is generally realized. The lesion's apparent rarity may be ascribed to limited awareness of the clinical appearance, combined with technical difficulty in obtaining suitable biopsy material for confirmation. A consequence of previous cervical trauma, endometriosis of the cervix can be expected to increase in incidence with more widespread use of invasive cervical procedures. Clinical recognition and tissue confirmation thus become essential. This paper refocuses attention on cervical endometriosis by documenting the clinical, colposcopic, and histopathologic findings in 16 cases seen at a single colposcopy clinic over a 6-month period. Diagnosis in these patients was facilitated and improved by fine needle aspiration cytologic testing. This technique, not previously used for documentation of endometriosis in this location, is outlined in detail, together with a full description and illustration of the cytologic features. (Am J Obstet Gynecol 1987;157:849-56.)

Key words: Aspiration, cytology, cervical endometriosis

Endometriosis of the cervix is usually regarded as an uncommon lesion, most gynecologic texts making only brief mention of its existence. After an initial observation by Fels[1] in 1928, only 12 single case reports had accumulated in the literature by 1952, when Ranney et al.[2] challenged the apparent rarity of the lesion with a series of 16 cases seen in a 4-year period. Further supportive evidence was provided by Williams,[3] who documented 111 cases in 1960. Both Ranney and Chung[2] and Williams[3] attributed the dearth of reported cases to lack of clinical awareness of the lesion, difficulty in obtaining adequate biopsy material, and poor recognition of the histologic features.

The classic "endometrioma" of the cervix is an obvious round, raised, hemorrhagic lesion, readily visible on speculum examination and easily sampled. Many of the lesions described by Ranney and Chung and by Williams were, however, small, nonprotuberant, and fragile. Superficially located on the tough, fibrovascular cervical stroma of the ectocervix, they were easily overlooked or readily ruptured and traumatized during attempts at punch biopsy. The resultant crushed tissue, containing a few fragmented glands or only sheared stroma, was often not recognized as being endometrial in type by the examining pathologist.

Development of endometriosis in this location is ascribed to previous cervical trauma, which was documented in 75% and 95%, respectively, of the cases of Ranney and Chung and of Williams. With increasing use of diagnostic and therapeutic traumatizing cervical procedures, as well as extended use of the colposcope since that time, a definite increase in reported cases of cervical endometriosis might have been expected. However, apart from smaller series published by Wolfe et al.[4] in 1961 and by Gardner[5] in 1962, no such documentation has been found in the English literature. Of all colposcopy texts consulted, only one, by European authors Dexeus, Carrera, and Coupez,[6] was found that alludes to and illustrates cervical endometriosis. It would thus appear that the previously disproved myth regarding the rarity of this lesion has resurfaced.

The purpose of this communication is twofold: to reintroduce the neglected topic of endometriosis of the cervix into the English literature by documenting 16 cases seen at a single colposcopy clinic over a 6-month period and furthermore to propose, for the first time, a new method of diagnosis—that of fine needle aspiration cytologic testing, which in our experience has provided a rapid, accurate, and relatively noninvasive method of confirmation of clinically and colposcopically suspicious endometriotic lesions of the cervix.

Patients and methods

Sixteen patients with verified cervical endometriosis, who form the basis of this report, were all seen at a

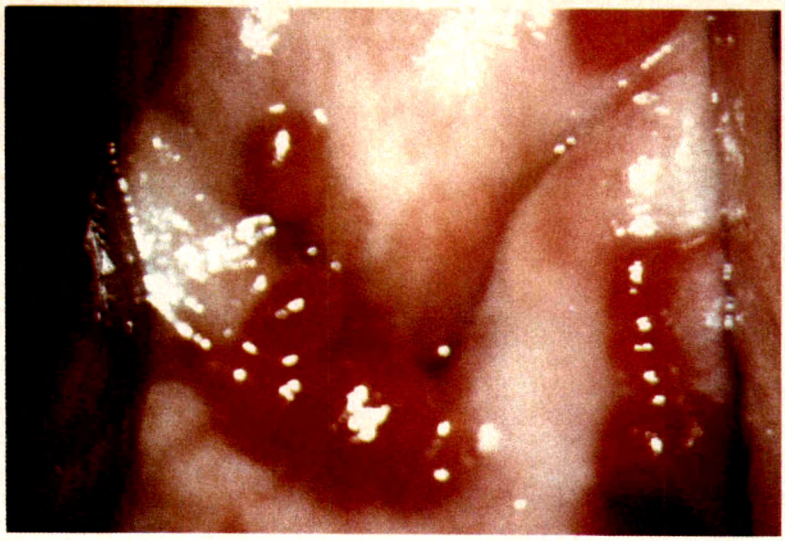

Fig. 1. Colpophotograph of cervical endometriosis seen 3 days before menstruation. Note multiple, irregularly shaped but well-delineated, raised, red, domed, submucosal nodules on the ectocervix. One large focus abuts on the external os but does not extend into the cervical canal. (Original magnification ×1.4.)

single colposcopy clinic during a 6-month period, during which a total of 670 patients underwent colposcopic examination by one author (M. M. V.-F.). Indications for colposcopic evaluation were abnormal cervical smears in nine, vaginal discharge in four, abnormal vaginal bleeding in three, and follow-up after previous conization in two. In all 16 patients, ectocervical lesions were identified either macroscopically or colposcopically and were strongly considered clinically to be endometriotic foci. In the first two patients seen, directed biopsies with standard punch biopsy forceps failed to provide histologic confirmation. In an attempt to obtain verification of the lesions seen, the technique of fine needle aspiration (previously successfully applied by the same colposcopist in two cases of rectovaginal endometriosis[7]) was performed by use of a standard 20 ml syringe and 21-gauge needle. The needle tip was introduced superficially into the cervical lesion, and gentle suction was applied by withdrawal of the plunger with the needle still in situ. The syringe and needle were then withdrawn, and the needle contents expelled and spread onto a plain glass slide, with a spray fixative used for rapid fixation. A small amount of hemorrhage occurred at the needle puncture site. This was used as a guide for immediate biopsy of the focus, which was generally less protuberant after needle aspiration. Subsequent bleeding from the biopsy site was not profuse in any of the cases and was controlled by direct pressure. In the laboratory, aspiration smears were stained by the Papanicolaou stain. The biopsy specimens were aligned, embedded in their entirety, and initially sectioned at two levels. This was soon shown to be inadequate, and ultimately an average of 12 levels was cut and examined from each specimen. All histologic specimens were stained with hematoxylin and eosin.

Initial colposcopic evaluations were performed during menstruation. Once the diagnosis of endometriosis was established, the patients were encouraged to return before or during menstruation. A total of 41 evaluations was performed on these 16 patients, of whom only three were not seen around the time of menstruation, their examinations being at midcycle.

Results

The 16 patients with cervical endometriosis represented 2.4% of patients undergoing colposcopic evaluation during that time period. All were black, their ages ranging from 23 to 45 (average 31). Within the group parity ranged from 0 to 5 (average 2.5). Of the total, 56% had previously documented cervical procedures, including cone biopsy in two, cervical curettage in six, laser therapy in three, and electrocautery in one.

Colposcopic findings. Marked variability was noted in the appearances of endometriotic foci of the cervix. All were characterized by a definite ectocervical location, with no encroachment on the squamocolumnar junction, even if close to the external os of the cervix. The lesions were submucosal, covered by epithelium with smooth, shiny characteristics of squamous epithelium, as opposed to red, granular appearances of endocervical epithelium, seen colposcopically (Fig. 1).

Size, shape, and color were evanescent, progressive, or regressive, depending on the stage of the menstrual cycle. In the three patients in whom examination was

Fig. 2. Colpophotograph of same cervix illustrated in Fig. 3. Seen at midcycle, the endometriotic foci are macular, hemorrhagic, small lesions situated on the ectocervix. (Original magnification × 1.4.)

Fig. 3. Colpophotograph of cervix illustrated in Fig. 2, seen 12 days later, 2 days before menstruation. The hemorrhagic areas remain flat but have spread to involve large areas of the ectocervix, sparing the area around the external os. (Original magnification × 1.4.)

possible only at midcycle, the lesions were macular and plaque-like, just slightly elevated from the contour of the ectocervix. In all patients seen around menstruation, the lesions were seen to enlarge, extend, and become dome-shaped, cystic, or nodular. The majority were round, but linear and serpiginous foci, generally with well-defined contours, were also seen. Toward the end of the menstrual cycle, individual lesions became confluent and in one patient assumed a widespread appearance, involving almost the entire ectocervix (Figs. 2 and 3). This was the only lesion that became ulcerative when seen after menstruation. The lesions were red or red-blue in color and acquired a mottled appearance close to menstruation. The smallest lesion seen measured <2.0 mm in diameter and was well visualized only through the colposcope. The average lesion size was 1.0 cm intermenstrually, extending to a diameter of 2.0 cm at maximum development. The larger lesions were easily seen macroscopically as erythematous areas. Neither scarring nor puckering was observed in any of the cases, and in none did the lesions extend into the vaginal fornices.

Cytologic appearances. In 10 of 14 patients on whom needle aspiration was performed, cellular features di-

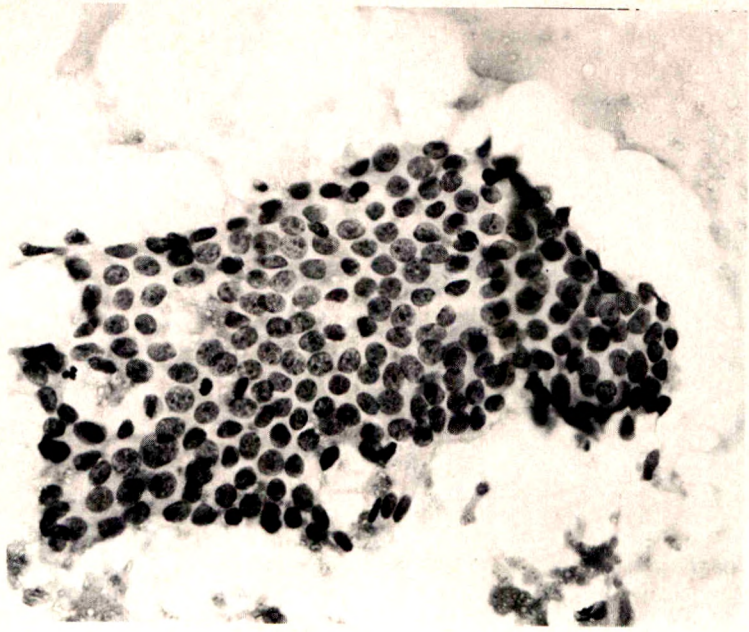

Fig. 4. Endometrial glandular cells in fine needle aspiration cytologic smear. Round-to-oval monomorphic cells form a monolayer sheet with poorly defined cytoplasmic borders. (Papanicolaou stain. Original magnification ×500.)

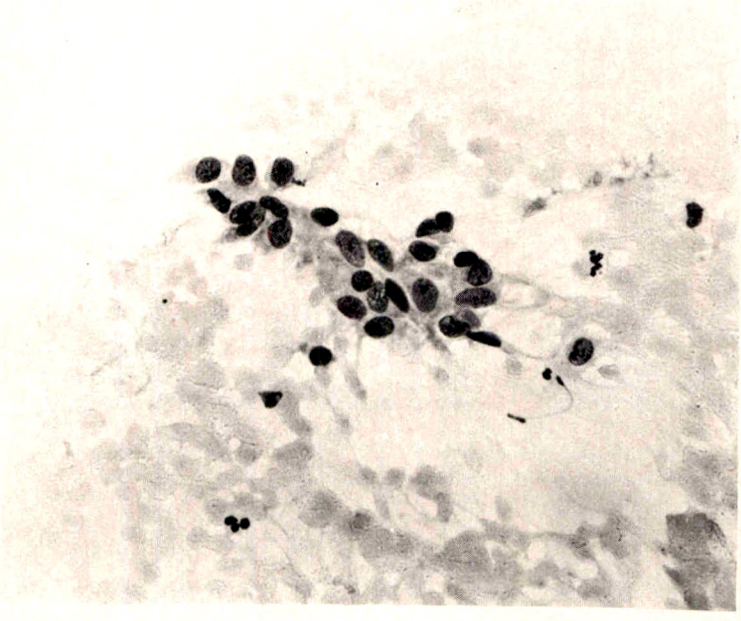

Fig. 5. Endometrial stromal cells in fine needle aspiration cytologic smear. Cells are elongated with abundant basophilic cytoplasm. Cytoplasmic borders are poorly defined in the loose aggregate. (Papanicolaou stain. Original magnification ×500.)

agnostic of endometriosis were found and provided the first confirmation of the clinical impression. Both endometrial glandular and stromal cells were present in eight of these 10 aspirates; one contained identifiable stroma only; one showed only glandular cells. In the remaining four cases, only blood and squamous cells from the overlying epithelium were seen. These four cases had verification on histologic examination. Endometrial glandular cells in needle aspiration specimens occurred in monolayer sheets (Fig. 4) or in small, more irregular clusters. In the flat sheets, nuclei were evenly dispersed, round, even, and vesicular, with small

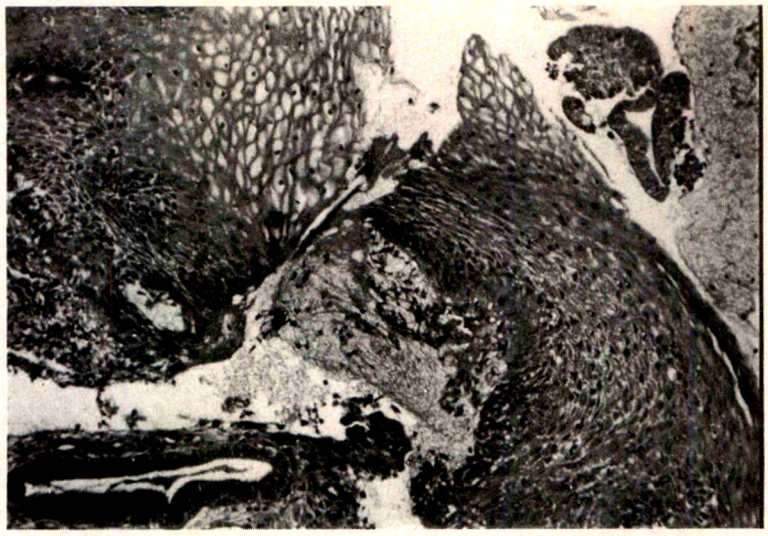

Fig. 6. Histologic section from a case in which the fine needle aspiration cytologic smear was nondiagnostic. The biopsy specimen was traumatized by the fine needle aspiration needle track extending through the ectocervical squamous epithelium into an endometriotic focus *(bottom left)*. Two clusters of aspirated endometrial glandular cells remain adjacent to the surface epithelium *(top right)* after failed suction. (Hematoxylin and eosin. Original magnification ×200.)

chromocenters and occasional small nucleoli. Sheets of this nature were distinguished from endocervical cells, which they resembled, by their smaller size and by absence of well-defined cytoplasmic borders. In the smaller groups, nuclear features were identical, but crowding resulted in nuclear molding and loss of polarity.

Endometrial stromal cells appeared as large syncytial fragments or as smaller groups of spindle-shaped cells, with more abundant cytoplasm than noted in glandular cells. Cytoplasmic outlines were poorly defined, but staining characteristics were uniformly basophilic. Some pleomorphism in nuclear size and shape ranging from oval to more spindle-shaped could be appreciated. Where well preserved, chromatin was granular but evenly dispersed (Fig. 5). Siderophages were seen in only four of the cases and were not required for definitive diagnostic purposes.

Sensitivity of diagnosis by fine needle aspiration cytologic testing was 71%, with 100% specificity. Absence of diagnostic cellular material was probably related to technical problems, as evidenced by a case illustrated (Fig. 6). No endometrial glandular or stromal cells were seen in the cytologic preparation. The biopsy performed simultaneously, however, showed the needle track leading to a submucosal focus of endometriosis. A cluster of cells, which had obviously been successfully aspirated from this focus, was seen in the section lying just above the ectocervical squamous epithelium. This in all probability resulted from the suction being released too suddenly, with loss of the cells from the needle.

Histologic features. A total of 23 biopsies was performed on various occasions on these patients. On routine examination, when two standard levels were cut from each block, only six of these cases were reported as showing histologic endometriosis. However, when aspiration cytologic results became known and the blocks were subjected to multiple serial sections, seven further lesions were found. The initial sensitivity of biopsy diagnosis was thus 26% with a final review sensitivity (alerted by cytologic results) of 57%.

The histologic features of endometriosis in these cases differed from that described for the classic "endometrioma" of the cervix mainly in terms of lesion size. Many foci measured no more than 2 to 3 mm in diameter or in depth, thus requiring multiple levels to ensure adequate demonstration. Initial sections frequently showed only a few red blood cells lying beneath the basement membrane of the ectocervix. With deeper sampling, characteristic endometrial stroma and glands became evident. The endometrial glands were lined by a single layer of cuboidal closely packed cells. Confusion with endocervical cells was obviated by marked ectocervical location and by absence of the neatly palisaded, tall-columnar appearance characteristic of endocervical cells. Glands were embedded in a stroma of varying cellularity, characterized by small round or oval cells and easily distinguished from the surrounding cervical stroma, which presented a less cellular, more fibrous appearance (Fig. 7). Areas of hemorrhage were frequently observed, but proliferative or secretory changes were less readily apparent. The needle track was usually incorporated in the biopsy specimen. One particular

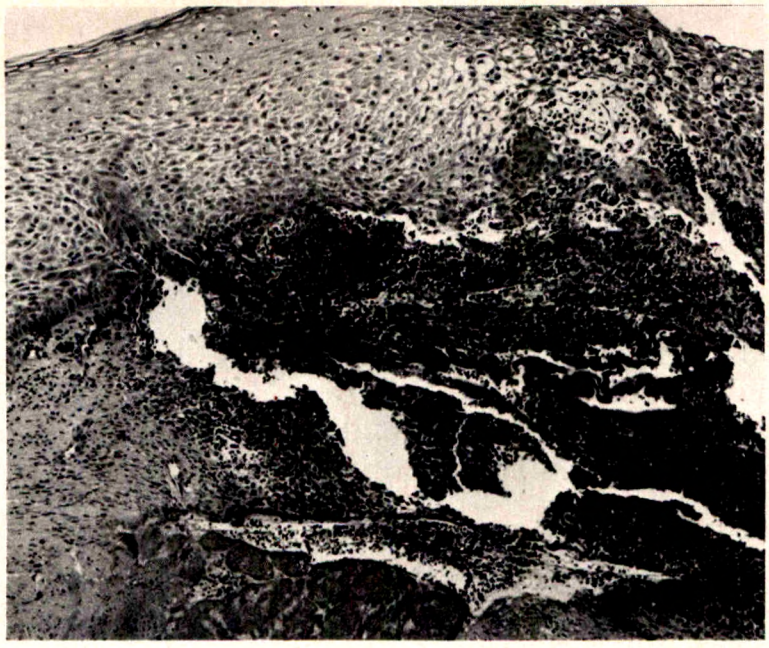

Fig. 7. Low-power view of cervical endometriosis traumatized by previous aspiration. The needle track is seen on the extreme right of the picture. Beneath the ectocervical squamous epithelium, cellular endometrial stroma and a single gland are seen. The endometrial stroma is readily distinguished from the more fibrous ectocervical stroma. (Hematoxylin and eosin. Original magnification ×125.)

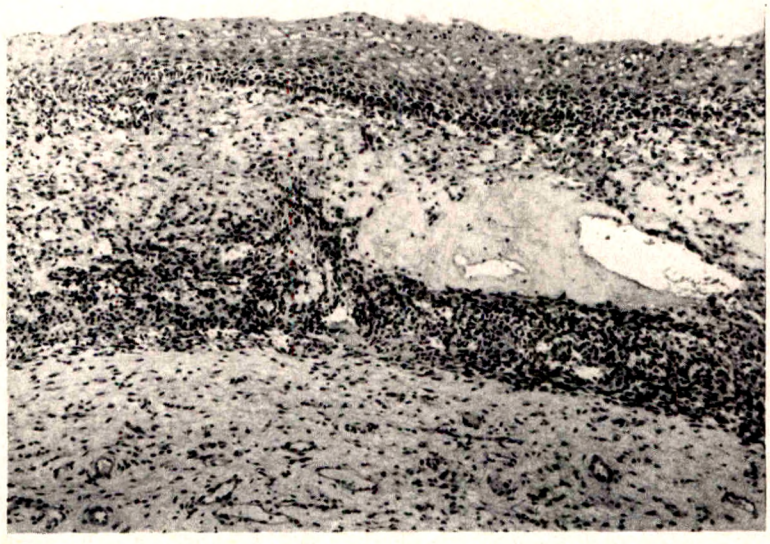

Fig. 8. Low-power section of case initially misinterpreted as showing cervicitis. A band of high cellularity lies between the basement membrane of the ectocervical squamous epithelium and the dense ectocervical stroma. Deeper sectioning revealed the picture shown in Fig. 9. (Hematoxylin and eosin. Original magnification ×125.)

lesion warrants further comment. The specimen was taken from the patient mentioned above in whom a spreading lesion encompassed almost the entire ectocervix before menstruation. This biopsy specimen had been misinterpreted as showing marked inflammatory changes at the time of first examination. After endometriosis was found on aspiration cytologic testing, this lesion was reexamined. As seen (Fig. 8), the initial

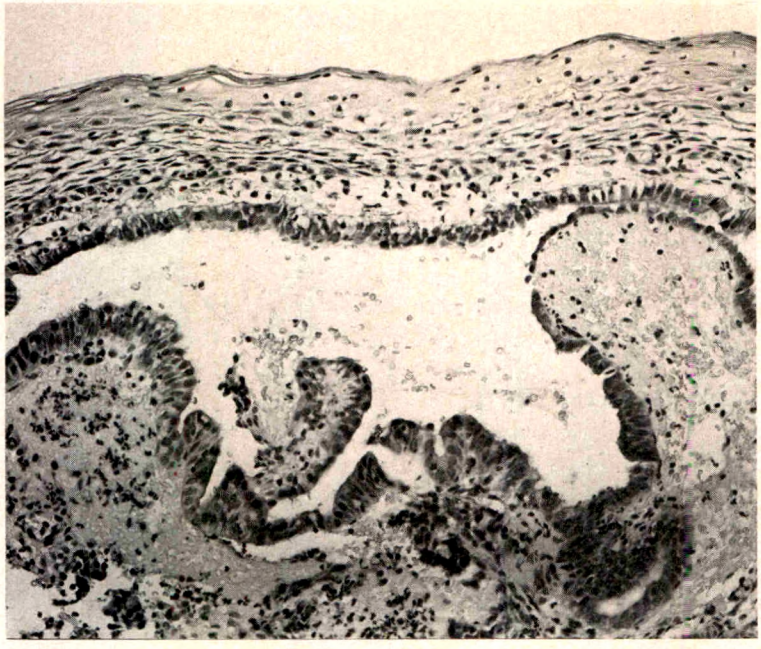

Fig. 9. Deeper sectioning of biopsy specimen shown in Fig. 8 shows endometrial glands immediately subjacent to the basement membrane of the squamous epithelium. (Hematoxylin and eosin. Original magnification ×200.)

impression is of a marked inflammatory infiltrate beneath the ectocervical epithelium. However, close inspection reveals that the band of cellular material consists of endometrial stroma and not of inflammatory cells. Deeper sections taken from this block subsequently demonstrated well-formed endometrial glands within this cellular stroma (Fig. 9).

Comment

Despite the pioneering work in the 1950s and 1960s,[2, 3, 8, 10] it would seem that the concept of cervical endometriosis as a not infrequent occurrence has been lost to later generations of gynecologists, colposcopists, and histopathologists. For this reason, almost 60 years after its first description,[1] it is still not possible to quote the incidence of this condition, nor is it known whether its frequency is rising, as might be expected with greatly extended use of cervical procedures such as conization, colposcopic biopsy, diathermy, and laser therapy. The only incidence figures quoted are by Dexeus et al.,[6] who tabulated the number of cases of cervical endometriosis observed in six European colposcopic series. The estimates ranged from 0.11% to 0.44%, but neither the populations nor the reasons for colposcopy were further defined. In our series of 670 black patients undergoing colposcopic evaluation for abnormal cervical smears, vaginal discharge, abnormal bleeding, or follow-up after conization, 16 had cervical endometriosis proven by aspiration cytologic testing, histopathologic examination, or both. This incidence of 2.4%, significantly higher than any previous estimate, is felt to be a consequence of heightened clinical awareness of the condition, together with intensified pursuit of a procedure whereby tissue confirmation could be obtained in the face of initial biopsy failures.

Fine needle aspiration of suspicious, elevated cervical nodules has, in this small series, been shown to facilitate and improve pathologic documentation. More extensive sectioning than is usual in laboratory specimens, prompted by cytologic findings, raised the sensitivity of histologic confirmation from 26% to 57%. The poor performance of punch biopsies in the study mirrors the experience of early authors. Ranney and Chung[2] noted that biopsies should be performed without causing trauma or crushing, and even with the best-quality tissue, the individual interpreting the slides should be "endometriosis conscious." Williams[3] observed that biopsy instruments that depended on crushing, shearing, or scraping would almost always fail to secure satisfactory tissue except from relatively large lesions. He advised that cold knife biopsy of suspicious lesions was the preferred method for obtaining diagnostic tissue.

Problems in obtaining optimal material can be obviated by utilizing fine needle aspiration cytologic testing as shown in this series. The ability to diagnose endometriosis in aspirated cytologic material from nonfluid foci has previously been documented in aspirates from endometriotic scars[9] and from the rectovaginal septum.[7] The association of small columnar cells in monolayer sheets or crowded clusters, together with more elongated stromal cells, is characteristic and specific. The sensitivity of cytology in this series, at 71%,

was higher than that of histopathologic diagnosis. Cytology also provided the first confirmation of many clinically suspicious lesions, thereby promoting a more intensive search for histopathologic verification.

Queries relating to the necessity for cell or tissue confirmation of what is apparently a recognizable and specific clinical lesion were answered by Williams,[3] who noted that endometriotic foci may be mimicked by hemorrhagic nabothian cysts, cervicitis with focal hemorrhage, hemangiomas, decidual reactions, and even malignant lesions. All these can readily be differentiated from endometriosis by an "endometriosis conscious" pathologist, and none would produce the characteristic dual cell population obtained by fine needle aspiration from a focus of endometriosis. In support of this, during this study period, two further patients were seen with colposcopic appearances suggestive of endometriosis. Cytologic results were negative in both cases. On histologic examination, one lesion was a hemorrhagic nabothian cyst, and the other contained postradiation petechiae. These examples highlight the need for cytopathologic diagnosis.

The clinical significance of endometriosis of the cervix has been addressed by Gardner and Kaufmann,[10] in whose experience it was considered one of the chief causes of persistent or recurrent minimal metrorrhagia, in particular, causing perimenstrual spotting and contact bleeding. Only two patients in the current series complained spontaneously of abnormal bleeding. The cervical lesions in all patients were isolated findings. None had evidence of internal pelvic or extrapelvic endometriosis on clinical examination. This is in keeping with the experience of all other authors. The fact that cervical foci in these patients appear to be isolated or "primary," without coexistent pelvic stigmas, as well as the known relationship of this lesion to previous cervical procedures, lends strong support to Sampson's theory of implantation as an etiologic mechanism.

Treatment remains problematic. If, as has been stated, cervical endometriosis is a potent source of intermenstrual bleeding, then treatment is clearly desirable. On the other hand, if its very existence is related to surgical procedures, further locally destructive therapeutic mechanisms such as excision or fulguration would create a potential for reimplantation and recurrence. While Williams and Richardson[8] claim successful treatment by light cauterization, Gardner and Kaufmann[10] document "surprisingly frequent" recurrence. No data are available on treatment by newer modalities such as cryotherapy or laser therapy.

More than half a century after its first description, cervical endometriosis remains poorly documented and little understood. In refocusing the attention of gynecologists and pathologists on this topic, we hereby wish to promote the use of fine needle aspiration cytologic testing as an inexpensive, atraumatic, sensitive and rapid method of diagnosis—a method that can avoid the difficulties of biopsy confirmation in many cases. The technique will, however, be of value only if the examining clinician and the pathologist maintain a high index of suspicion and redevelop an awareness of both the existence and appearance of cervical endometriosis, well documented many years ago.

A novel Y/13 familial translocation

Michael I. Morris, Ph.D., Frederick W. Hanson, M.D., and Frances R. Tennant, Ph.D.
Sacramento, California

A novel Y/13 translocation was discovered in a female fetus during amniocentesis. The familial translocation is present in a phenotypically normal female sibling and in the father who also possesses a pericentric inversion. Karyotype of the father is 46,XY, − 13, + der(13)t(Y;13)(q12;p12),inv(22)(p13q12.1).
(AM J OBSTET GYNECOL 1987;157:857-8.)

Key words: Y chromosome, autosome 13, translocation

Reports of translocations between the Y chromosome and autosomes (numbers 13, 14, and 15) of the D group have accumulated slowly over the past 15 years. The frequency of Y/15 translocations has been found to greatly exceed the combined occurrence of Y/14 and Y/13 exchanges.[1] The incidence of the Y/14 type approximates that of the Y/13 type.

Although less than 10 cases* of Y/13 translocation have been reported, the nature of chromosomal transposition and the consequence of clinical manifestation vary among them. Nearly all these cases involved males who had diverse phenotypic expressions, such as subfertility, mental retardation, encephalocele, bilateral clubfoot, or a variety of other congenital anomalies. Karyotypes of most of these patients were either unbalanced or incompletely ascertained because of an inability to specify exact breakpoints in the translocated chromosomes. Reports of Y/13 translocations in females with completely documented karyotypes are extremely rare and appear to be limited to a single case described by Vianello et al.[2]

Case report

A routine amniocentesis that was performed during late 1986 on a patient at our prenatal diagnosis facility at the University of California, Davis, Medical Center resulted in a fetal karyotype believed to be of novel designation: 46,XX, − 13, + der(13)t(Y;13)(q12;p12)pat. Single cells from 15 colonies of amniocytes all revealed the same karyotype (under GAG/GTG methods), which indicates that breakpoints occurred at bands q12 and p12 in the long and short arms of chromosomes Y and 13, respectively. Segments distal to these bands have been reciprocally exchanged between the two chromosomes. The use of NOR, CBG, and QFQ banding techniques showed that the additional material on the p arm of one number 13 autosome is C and Q band positive and NOR negative. Thus the brightly fluorescent Q positive material indicates the presence of Y material on autosome 13. Because this Y/13 translocation is also found in the clinically normal father of the fetus (mother is 46,XX), as well as in a normal 1-year-old female sibling, the karyotype is considered a familial variant and probably lacks clinical significance, although sexual development in both the infant and impending neonate will be followed. The father's genome also contains a pericentric inversion in chromosome 22. Thus this novel karyotype can be designated as 46,XY, − 13, + der(13)t(Y;13)(q12;p12),inv(22)(p13q12.1).

Comment

This study differs from that of Vianello et al.[2] in at least three aspects. First, our study confirms that the breakpoint in autosome 13 is at band p12, whereas Vianello et al.[2] indicate that the autosome 13 breakpoint could be either p11 or p12. Second, in their study, the father of the patient lacked the inversion identified in the father of our patient. Third, Vianello et al.[2] reported a complete palatolabioschisis, low-set ears, and a malformation of the right ear in their Y/13 female, whereas our Y/13 patients have been adjudged to be clinically normal.

The presence of the Yq12 segment in a normal female appears to have little effect on sexual development, and the prognosis for normal sexual development in both the fetus and 1-year-old patient may be considered good. The reason for this is that the Yq12→Yqter portion of the Y chromosome consists of constitutive heterochromatin, which lacks genes for maleness. Thus male-determining factors on the Y chromosome probably reside outside of the Yq12 region.

In vitro training model for diagnostic and therapeutic fetal intravascular needle puncture

Ilan E. Timor-Tritsch, M.D., and Ming-Neng Yeh, M.D.

New York, New York

An in vitro model, simple to assemble, consisting of a fresh placenta suspended in a water bath, is presented for the training of physicians interested in practicing ultrasound-guided fetal intravascular needle placement. (Am J Obstet Gynecol 1987;157:858-9.)

Key words: Fetal blood sampling, fetal intravascular procedures, ultrasound-guided needle puncture

Ultrasound-guided fetal blood sampling through the umbilical vein was first introduced by Daffos et al.[1] in 1983.

Direct access to the fetal vascular compartment opens wide possibilities for antenatal diagnosis, therapy, and clinical research.[2]

Despite the large potential, this procedure is used only by a handful of skilled, scientifically oriented clinicians because it requires special skill and experience by the operator. This skill is earned almost entirely by experience, which, in turn, increases proportionately with the growing number of procedures performed. In any given center, there may not be a large enough number of pregnant patients requiring fetal blood sampling or intravascular transfusions, thereby making it difficult to acquire skill and excellence. This, of course, hampers the training of others.

To overcome the problem of physician training, we developed an in vitro model to perform ultrasound-guided umbilical vessel puncture.

Material and method

A recently delivered intact placenta with the cord clamped at 20 cm from its placental insertion was used. Heparin was injected through both the umbilical veins and the artery one at a time and mixed thoroughly with the blood by repeated aspiration and reinjection by means of a 20 ml syringe. At the end of this procedure, the cord was clamped by a Hollister clamp after the

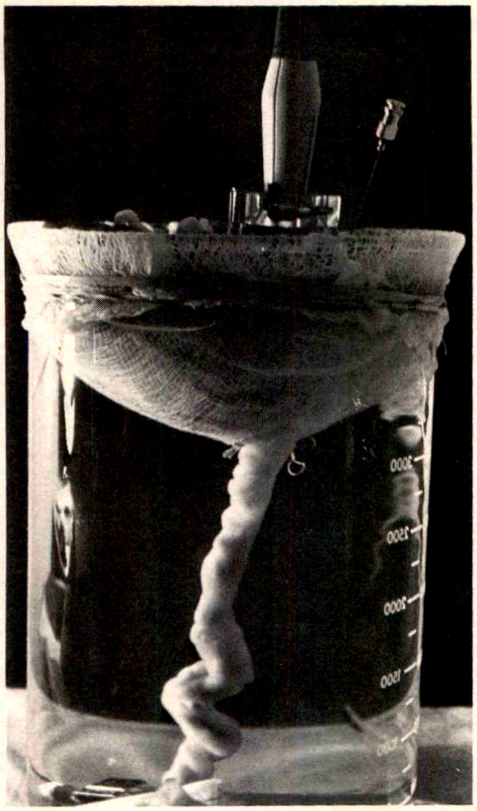

Fig. 2. Placental model.

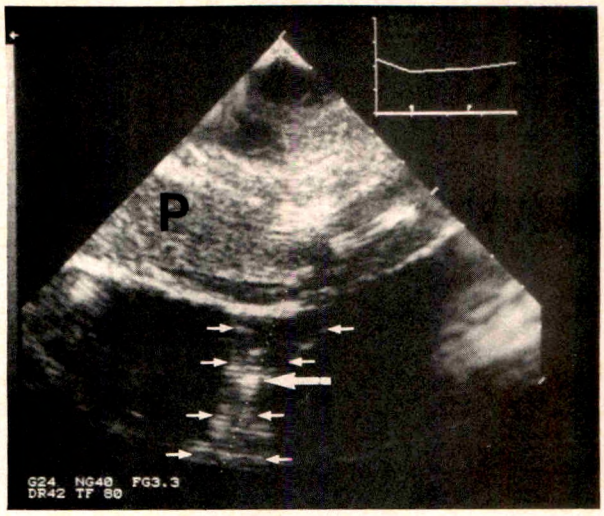

Fig. 3. Ultrasonographic picture of the model. (*P* = Placenta; *small arrows* = umbilical cord; *large arrow* = needle tip.)

fetal aspect of the placenta was inspected to ensure the presence of engorged and blood-filled vessels to represent in vitro anatomy. The placenta was suspended by a gauze "hammock" in a water-filled tank. The water should be left to settle for 30 minutes to get rid of microbubbles that would otherwise interfere with the scanning. The cord was threaded through a small opening in the middle of the "hammock" and fastened to a heavy object to prevent free floating of its clamped end.

The schematic illustration of the setup is shown in Fig. 1. After the tank was filled with additional water, the scanning is started with a sector-scanning probe fitted with the needle guide attachment (Fig. 2). The proper section and direction for needle placement are selected and aligned with the software generated needle path line on the screen. The needle is gently advanced under ultrasound guidance into the target vessel (Fig. 3). An attempt is then made to withdraw blood. If successful, the tip of the needle should be inspected through the transparent glass tank by gently moving it to touch the vessel wall. This movement of the needle tip is visible and enables correlation of the sonographic image with the actual position of the needle. If the vessel wall is punctured and water is aspirated, the site of perforation should be inspected to complement the on screen needle positioning with that in situ. The correct needle placement should be undertaken after this.

A posterior or lateral cord insertion can be simulated by positioning the placenta on the bottom or the lateral wall of the tank with the cord pointing upward or sideways, respectively. A different way to prepare the model is to flush the umbilical vessels and replace the blood with a diluted methylene blue solution. However, we suggest keeping the blood already within the vessel because it presents the authentic feeling of aspirating fetal blood through the thin needle at the time of a true sampling procedure.

One should start with a term placenta and gradually use placentas originating from pregnancies with younger gestational ages. The aim is to be proficient enough to successfully sample fetuses before reaching the gestational age at which an indicated termination of the pregnancy is prohibited by law.

Comment

A fetal blood sampling model was described and suggested for in-service training of perinatologists who wish to become proficient in this method.

The advantages of this model are: (1) It is simple to assemble, (2) it is inexpensive, (3) placental supply is abundant, and (4) no lengthy review by institutional human investigation committees is required.

After the method of intravascular needle placement is mastered, it is possible to use this model and proceed to more complex tasks of transfusing fluid or performing exchange transfusions.

Antepartum fetal surveillance in the patient with decreased fetal movement

Myoung Ock Ahn, M.D., Jeffrey P. Phelan, M.D., Carl Vernon Smith, M.D., Nancy Jacobs, R.N., and Susan E. Rutherford, M.D.

Los Angeles, California

Whenever a patient has the subjective perception of decreased fetal movement, prompt evaluation in the form of antepartum fetal surveillance has been undertaken. The purpose of this report is to describe our experience with 489 pregnant women who came between Jan. 1 and Dec. 31, 1985 to our Antepartum Fetal Surveillance Clinic with this complaint alone or in association with another indication for fetal surveillance. Overall, 838 nonstress tests were performed, and the results were reactive, 93.2%; nonreactive, 6.8%; and fetal heart rate decelerations, 6.1%. Comparison of the first nonstress test results between those with decreased fetal movement alone or in combination with another diagnosis demonstrated a similar incidence of nonreactivity and fetal heart rate decelerations. In those patients whose indication was decreased fetal movement alone, there was a 3.7 times greater likelihood of diminished amniotic fluid volume. When the last test within 7 days of delivery was analyzed, the decreased fetal movement alone group had a lower incidence of cesarean delivery, cesarean delivery for fetal distress, and Apgar scores <7 than patients with an additional indication for testing. In summary, decreased fetal movement continues to be an acceptable indication for fetal surveillance. Based on our retrospective experience, the most reasonable approach appears to be a combination of nonstress test and amniotic fluid volume assessment. Unless the patient has additional indications for fetal surveillance, the patient with decreased fetal movement with a reactive nonstress test and a normal amniotic fluid volume does not appear to warrant additional testing. (Am J Obstet Gynecol 1987;157:860-4.)

Key words: Decreased fetal movement, antepartum fetal heart rate testing, amniotic fluid volume assessment, fetal acoustic stimulation

Between 16 and 20 weeks of pregnancy, the pregnant woman first perceives fetal movement. Although normal fetal movements are considered a sign of fetal well-being, decreased or absent fetal movement can be a sign of fetal jeopardy.[1] Previous investigators[1, 2] have demonstrated a relationship between decreased fetal movement and fetal distress or impending fetal death. This has been especially true in the high-risk pregnancy.[2] However, Milliez et al.[3] could find no correlation between the absence of fetal movements and subsequent fetal outcome. Nonetheless, these investigators found a less favorable outcome when fetal heart rate accelerations were absent.

However, little information is available concerning the relationship between the results of antepartum fetal surveillance testing and the patient who has the complaint of decreased fetal movement. Therefore the purpose of this retrospective investigation was to describe our experience with antepartum fetal surveillance testing in this group of patients.

Material and methods

From Jan. 1, 1985 through Dec. 31, 1985, all patients who came to the Antepartum Fetal Surveillance Clinic at the Los Angeles County/University of Southern California Medical Center with the subjective complaint of decreased fetal movement were reviewed. During this period, 489 patients underwent 838 nonstress tests for decreased fetal movement alone or in combination with another indication. Outcome data were based on all patients who delivered within 7 days of their last nonstress test.

All fetal surveillance tests were performed by full-time antepartum-testing nurses trained in ultrasonography and fetal monitoring. These tests primarily included a nonstress test, amniotic fluid volume assessment by means of a four-quadrant technique, or biophysical profile. Results of the fetal surveillance test were confirmed by a Maternal-Fetal Medicine Division staff member or fellow.

Table I. Indications for antepartum fetal surveillance in a group of patients with decreased fetal movement (January to December 1985)

Indication	Overall (N = 184)		Known outcome* (N = 127)

Suspected intrauterine growth retardation	10	5.4	5	3.9
Other	15	8.1	6	4.7

*Delivery within 7 days of the last test.

The procedure, criteria for the performance, and interpretation of the nonstress test have been previously described.[4] During the period of investigation, the primary technique used to establish a reactive nonstress test was transabdominal acoustic stimulation of the fetus with an electronic artificial larynx. In brief, transabdominal stimulation overlying the vertex is done for ≤3 seconds. If the fetus is unresponsive, the stimulus was repeated two additional times for a total of three stimuli. The criteria for a reactive nonstress test were the presence of two or more fetal heart rate accelerations of at least 15 bpm lasting a minimum of 15 seconds within a 10-minute window. Nonreactive nonstress tests were defined when the criteria for reactivity were not met within a 40-minute monitoring period.

If a test was interpreted as nonreactive, a fetal biophysical profile[5] or contraction stress test was used. Fetal heart rate decelerations were defined as a decline of the fetal heart rate from baseline of 15 bpm lasting 15 or 30 seconds if the deceleration immediately followed an acceptable acceleration (15 bpm × 15 seconds).

Amniotic fluid volume was assessed by the four-quadrant technique or amniotic fluid index previously described by Phelan et al.[6] In brief, the uterus is divided into four separate quadrants with the patient in the supine or semi-Fowler position. The uterus is divided into upper and lower halves by an imaginary line that traverses the umbilicus transversely. Then by using the linea nigra as the midline, the uterus is further divided into right and left halves. The transducer head is placed along the maternal longitudinal axis, perpendicular to the floor. The vertical diameter of the largest fluid pocket is identified and measured in centimeters for each quadrant. The summation of measurements from each quadrant represented the amniotic fluid index in centimeters for each patient. Simultaneously, placental location was determined during ultrasonographic evaluation.

Table II. Nonstress tests results for patients with decreased fetal movement alone (group I) or in combination with another indication (group II)

Nonstress test result	Overall			
	Group I (N = 390)		Group II (N = 448)

Reactive	358	91.8	423	94.4
Nonreactive	32	8.2	25	5.6

Table III. Nonstress test results at the time the patient complained of decreased fetal movement

Nonstress test result	No.	%
Reactive	458	93.7
Nonreactive	31	6.3

Pregnancy outcome was measured by incidences of meconium, fetal distress that required cesarean delivery, Apgar scores <7 at 1 and 5 minutes, abnormal cord positions (nuchal or truncal cord, a true knot, and funic presentation), and perinatal death.

Data were analyzed by dividing the study population into two groups; decreased fetal movement alone (group I) and decreased fetal movement with another indication (group II). Regarding the amniotic fluid index, the patients were subdivided into two groups: 0 to 5.0 cm and >5.0 cm.

Results

During the study period, antepartum fetal surveillance was performed on 489 patients who had a com-

*$p < 0.05$.

plaint of decreased fetal movement. Of these patients, 220 (45.0%) were delivered within 7 days of their last evaluation. Of the 489 patients, 163 (33.3%) had additional indications for a nonstress test and 112 (69%) delivered within 7 days of their last test. Table I demonstrates the indications for a nonstress test in these patients. Several patients had more than one indication for evaluation. Even though 31% delivered more than 7 days after their last test, the indications for the outcome group were similar to the overall group.

A total of 838 nonstress tests were performed on 489 patients. Of these, 781 (93.2%) were considered reactive. Table II demonstrates nonstress test results for the two groups: decreased fetal movement alone (group I) and decreased fetal movement with another indication (group II). Fetal heart rate decelerations were found in 51 of 838 tests for an incidence of 6.1%. On the day the patient was tested for decreased fetal movement, 93.7% of the nonstress tests were reactive (Table III). There was no significant difference in nonstress test results in terms of reactivity or the presence of fetal heart rate decelerations between the groups.

Table IV illustrates the relationship between the nonstress test results and the amniotic fluid index. In those patients with an amniotic fluid index ≤5.0 cm, nonreactivity ($p < 0.1$) and the presence of fetal heart rate decelerations ($p < 0.01$) were higher. On the day the patient first complained of decreased fetal movement, those patients whose only indication for testing was decreased fetal movement had a 3.7 times (3% versus 11%) greater likelihood of a diminished amniotic fluid volume.

Placental location was recorded during each ultrasonographic evaluation. On review, no significant difference between anterior and posterior placental locations was found between the two study groups.

The pregnancy outcomes for the two study groups are summarized in Table V. In those patients with decreased fetal movement alone, the cesarean section rate was lower in group I than in group II (13.0% versus 28.6%). Although the incidence of meconium was comparable for both groups, cesarean section rates for fetal distress were 3.7 versus 6.0% for groups I and II, respectively.

Fetal outcome, as measured by Apgar score and perinatal mortality, showed that group I had a 50% lower incidence of Apgar scores <7 at 1 and 5 minutes than did group II. During the study period, one perinatal death occurred (group II). The patient was a 31-year-old woman, gravida 6, para 5-0-0-5, at 31 weeks' gestation who underwent antepartum surveillance for decreased fetal movement and preeclampsia: the nonstress test was nonreactive. Subsequently, she delivered a 1470 gm male baby by cesarean section for fetal dis-

tress caused by a prolonged fetal heart rate deceleration. Apgar scores were 1, 5, and 7 at 1, 5, and 10 minutes, respectively. At delivery, the infant was noted to have multiple congenital anomalies and died on the eighth day of life.

Comment

Although frequently criticized, the subjective perception of fetal movements is the oldest and least expensive means of assessing fetal well-being. With ultrasonography, fetal movements can be detected as early as the seventh week of pregnancy. The objective and subjective perception methods of fetal movements have been well described by Sadovsky and Polishuk.[7] These movements have been characterized as weak, rolling, or strong. Rolling and strong movements increase progressively until 36 to 37 weeks' gestation. At that time, these movements decline and weak movements increase in frequency. Although the weak movements were still perceptible by the gravida, they were sensed less frequently than the strong or rolling movements.[8] During the third trimester, the normal fetus also exhibited some form of trunk, limb, or respiratory movement 10% of the time. However, diurnal variations,[9] maternal glucose concentrations,[9] and acoustic stimulation[4] may alter the frequency of fetal activity. In general, daily fetal movements continue to increase after 18 weeks' gestation and become maximal between 19 and 38 weeks' gestation. Thereafter, both the number of movements and the maternal perception of those movements decrease until delivery.

Previous methods to assess fetal well-being in cases of decreased fetal movement have primarily been biochemical.[9] However, decreased fetal movement is currently one of the more common indications for antepartum fetal surveillance.[4] Although decreased fetal movement is subjective and varies among pregnant women, a decrease in activity of a previously active fetus may symbolize fetal jeopardy.[7]

Although Sadovsky and Polishuk[1] have emphasized that decreased fetal movement is considered a sign of fetal distress, other investigators[3, 10] have reported cases of absent fetal movement with a normal outcome. O'Leary and Andrinopoulos[11] prospectively evaluated the relationship of the nonstress test and daily fetal movement recording for assessing fetal well-being. They found the presence of daily fetal movement neither sensitive nor specific for the detection of antenatal fetal jeopardy in high-risk pregnancies. These investigators failed to identify a relationship between nonstress test results and prior fetal movement pattern. In the current investigation, nonstress test results were also comparable with those reported by O'Leary and Andrinopoulos.[11]

Recent attention has focused on the importance of amniotic fluid volume assessment as an indicator of fetoplacental function[12] and fetal well-being.[13] With the use of real-time ultrasonography, several investigators have demonstrated a relationship between a decrease in amniotic fluid volume and subsequent fetal outcome.[13, 14]

Rayburn[15] previously hypothesized that a gradual decrease in the total amount of fetal motion after the thirty-second week may relate to a variety of conditions, including decreased amniotic fluid volume. Our investigation, which demonstrated a higher incidence of decreased amniotic fluid volume in the patient who had decreased fetal movement, would support Rayburn's theory. Moreover, when the fetal surveillance findings were normal, the current study demonstrated that a more favorable pregnancy outcome was found in the decreased fetal movement alone group than in those patients with additional indications for testing.

In summary, when a pregnant woman perceives decreased fetal movement, antepartum fetal surveillance is indicated to assess fetal well-being. Based on the current study, both nonstress test and some form of amniotic fluid volume assessment appear warranted. If the nonstress test is reactive, the amniotic fluid volume is normal, and the patient has no other indications for testing, follow-up testing does not appear indicated.

Validity of intrapartum diagnosis of fetal thrombocytopenia

Godelieve C. M. L. Christiaens, M.D., Ph.D., and Frans M. Helmerhorst, M.D., Ph.D.
Utrecht and Leiden, The Netherlands

Performing a platelet count in fetal scalp blood was hitherto the only method to predict whether the infant of a mother with idiopathic thrombocytopenic purpura will be thrombocytopenic. Fifteen such cases are reported. Falsely low platelet counts were found in almost half of these fetal scalp samples. In two patients this could have altered the obstetric management. (Am J Obstet Gynecol 1987;157:864-5.)

Key words: Idiopathic thrombocytopenic purpura, fetal scalp blood, platelet count

Idiopathic thrombocytopenic purpura is an immunologically mediated destructive thrombocytopenia. Maternal autoantibodies can cross the placenta and cause thrombocytopenia in the fetus. Several investigators have tried to find parameters to predict the occurrence and the degree of neonatal thrombocytopenia in order to decide on the less traumatic route of delivery. However, a relationship between the number of maternal and neonatal platelets could not be found. Also data on the correlation between the quantity of free and platelet-bound maternal autoantibodies, on the one hand, and the number of fetal platelets, on the other hand, are conflicting. Platelet counts in a micro

blood sample obtained from the fetal scalp have therefore been advocated as a method to identify the thrombocytopenic fetus.[1, 2]

Fetal scalp blood platelet counts were performed as part of a collaborative Dutch study on idiopathic thrombocytopenic purpura and pregnancy. Data on fetal and neonatal blood are available from 15 pregnancies. In order to prevent measuring errors due to adhesion of platelets to the sampling devices, the participating centers (n = 10) were instructed to use siliconized glass or plastic pipettes for fetal blood sampling, to transfer the blood immediately to a reservoir containing ethylenediaminetetraacetic acid, and to measure the number of fetal and/or neonatal platelets in an electronic blood cell counter. All gynecologists were experienced with the technique. Patients in whom clotting of the blood sample occurred were not included.

The data obtained are summarized in Table I. A difference of more than 35% was seen in seven of the 15 patients. Platelet counts were more than 50×10^9/L lower in fetal scalp blood than in neonatal blood in six of these cases. Previous publications on this subject show data for a total of 27 patients with idiopathic thrombocytopenic purpura and eight healthy pregnant women.[1, 2] In 11 of these cases there was a difference in platelet count of more than 50×10^9/L between fetal scalp blood and neonatal blood, with 10 of the fetal scalp samples yielding falsely low values and one a falsely high value. In the latter case platelet counts were above 250×10^9/L both in fetal scalp blood and in neonatal blood.[1] Our data and those from the literature hence show that in adequately sampled and analyzed fetal scalp blood, the thrombocytopenic fetus will be correctly identified. As to the falsely low values, two of the six in our series and none in the literature were below 50×10^9/L, the lower limit above which vaginal delivery is generally considered safe. This means that in two of the 15 patients from our series the obstetric management could have been altered unjustly because of falsely low fetal scalp platelet counts.

We conclude that the technique remains clinically useful to exclude thrombocytopenia in the child to be born but that falsely low values with consequences for obstetric management may occur in a small percentage of cases.

Effects of maternal glucose infusion on fetal acid-base status in human pregnancy

Elliot H. Philipson, M.D., Satish C. Kalhan, M.B., Margo M. Riha, R.N., and Renato Pimentel, M.D.

Cleveland, Ohio

The maternal and fetal metabolic effects of three commonly used intravenous fluids administered before regional anesthesia were studied in 32 gravid women undergoing elective cesarean section at term. Patients were randomized into one of three groups to receive 1 L of either 5% dextrose (50 gm of glucose) or Ringer's lactate or isotonic saline solution before epidural anesthesia. Acute glucose infusion resulted in maternal hyperglycemia, hyperinsulinemia, and an increase in the blood lactate level. Cord blood glucose, insulin, and lactate levels were also increased in this group. The key finding of this study was the significant lowering of pH in the umbilical cord vein (7.31 ± 0.04) and artery (7.21 ± 0.06) in the glucose-infused group when compared with the non–glucose infusion groups ($p < 0.05$). Confounding perinatal factors such as maternal position, maternal hypotension, and prolonged time of surgery did not influence the fetal acid-base status. Thus acute maternal glucose infusion in normal patients can cause fetal hyperglycemia, metabolic acidosis, and neonatal hypoglycemia. These findings may be of particular clinical importance when fetal distress or fetal hypoxemia is due to other perinatal events. Under these circumstances, acute maternal glucose infusion may further contribute to fetal metabolic acidosis.
(Am J Obstet Gynecol 1987;157:866-73.)

Key words: Pregnancy, intravenous fluids, glucose, fetal acidosis, hyperglycemia

Acute intravenous fluid administration has been recommended to prevent maternal hypotension by expanding volume during regional anesthesia.[1,2] Although this "prophylactic" hydration can be accomplished with various intravenous solutions, acute administration of fluids containing glucose can result in maternal and fetal hyperglycemia and hyperinsulinemia.[3,4] In well-oxygenated fetal lambs, sustained fetal hyperglycemia resulted in increased fetal lactic acid and decreased blood pH. More marked hyperglycemia caused severe metabolic acidosis.[5] Philipps et al.[6,7] demonstrated that sustained fetal hyperglycemia decreased fetal arterial oxygen concentration and induced a state of accelerated fetal oxidative metabolism. Direct insulin infusion to the fetus increased umbilical glucose uptake and decreased fetal arterial oxygen concentration.[8] In contrast to these chronic animal experiments, acute infusion of insulin increased fetal glucose uptake and utilization but did not alter fetal oxygen consumption.[9] Therefore it appears that chronic hyperglycemia and hyperinsulinemia influence glucose uptake, arterial oxygen concentration, and pH, whereas the effects of acute hyperglycemia may not be similar.

In human pregnancy, Kenepp et al.[10] reported that rapid infusion of large amounts of dextrose may be harmful to the fetus and of no benefit to the mother. In their study of women undergoing cesarean section, acute maternal glucose infusion (57.5 gm) resulted not only in maternal and fetal hyperglycemia and hyperinsulinemia but also in a significant decrease in fetal pH. However, intrapartum and perinatal confounding factors other than maternal glucose could have influenced fetal acid-base status. Placental hypoperfusion, as a result of maternal hypotension or maternal supine position, can cause lactic acidosis and influence neonatal acid-base balance at birth.[2,11] In addition, prolonged surgical intervals, that is, the time between induction of labor and delivery of the fetus or the time from myometrial incision to delivery, can influence the incidence of neonatal acidosis and low Apgar scores.[12,13] Therefore the purpose of this prospective randomized study was: (1) to evaluate the maternal and fetal metabolic effects of three intravenous fluids commonly used to prevent maternal hypotension during regional anesthesia and (2) to examine intrapartum perinatal factors that could influence fetal acid-base status.

Values are mean ± SD.

Methods and material

All patients had normal, singleton, term gestations and were scheduled for elective cesarean section at Cleveland Metropolitan General Hospital. Patients with liver or kidney disease or any medical complications were excluded from the study. All patients had a negative screening test for diabetes mellitus. After written informed consent was obtained, patients were assigned by a random table of numbers into one of three groups. Group 1 patients received 1 L of 5% dextrose in water (glucose = 50 gm); group 2 patients received 1 L of Ringer's lactate; group 3 (control) patients received 1 L of normal saline solution. The intravenous fluids were administered rapidly during 20 to 30 minutes. Immediately after the hydration, all patients were maintained on a regimen of intravenous normal saline solution at a rate of 125 ml/hr until surgery and delivery of the baby.

Epidural anesthesia was then induced with 0.5% or 0.75% bupivacaine without epinephrine. All patients were placed on the operating room table in the supine position with left lateral uterine displacement and received oxygen at 4 L/min by nasal cannula. Maternal blood pressure was measured every minute with an Arteriosonde (Kontron Inc., Everett, Mass.) from the time of epidural anesthesia until delivery of the infant and every 5 minutes thereafter. Maternal hypotension (a decrease in the systolic blood pressure of >30 torr from baseline or an absolute level <100 torr) was corrected by incremental doses of intravenous ephedrine (5 to 10 mg) and by increasing the rate of infusion of normal saline solution.

Maternal blood samples (3 ml each) were obtained from an indwelling cannula in a peripheral hand vein. The sampling site was kept patent by a heparin lock. In order to obtain arteriolized samples, the sampling site was kept warm (55° C) by a heating blanket. Maternal blood samples were obtained at the start of and after acute intravenous hydration at 10, 20, and 30 minutes and continued every 10 minutes until delivery. Fetal arterial and venous blood samples were obtained at birth from a double-clamped umbilical cord. Neonatal blood samples were also obtained every 30 minutes for 2 hours by venipuncture or heel stick. Since the amount of blood drawn from the infant was limited, the samples at 90 and 120 minutes were analyzed for glucose only. All blood samples were obtained in heparinized syringes and immediately placed on ice. Plasma was separated and stored at −10° C for later analysis. An aliquot of whole blood was precipitated with chilled 10% perchloric acid for lactate measurement.

The data collected during the study also included the skin–to–delivery time interval and the uterine incision–to–delivery interval. At birth, 1- and 5-minute Apgar scores were recorded. Each infant was weighed and a complete physical examination was performed. The gestational age was determined by a modification of the Dubowitz examination by Ballard et al.[14]

Blood samples were analyzed for glucose, lactate, insulin, ketones (β-hydroxybutyrate), and triglycerides. Maternal samples were analyzed for electrolytes, carbon dioxide, and blood urea nitrogen. The baseline maternal samples and umbilical cord samples were also analyzed for acid-base status (pH, P_{CO_2}, P_{O_2}, and base deficit). Blood gas tensions and pH were measured with a microelectrode system (Model 13031, Instrumentation Laboratory, Lexington, Massachusetts). Plasma glucose was measured by a coupled enzymatic assay with the use of hexokinase and glucose-6-phosphate dehydrogenase on an automated centrifugal analyzer (Baker Instruments, Pleasantville, New York). Blood lactate, β-hydroxybutyrate, and triglycerides were measured by enzymatic methods and insulin by a double-antibody radioimmunoassay. All the assay methods have been previously reported from this laboratory.[15]

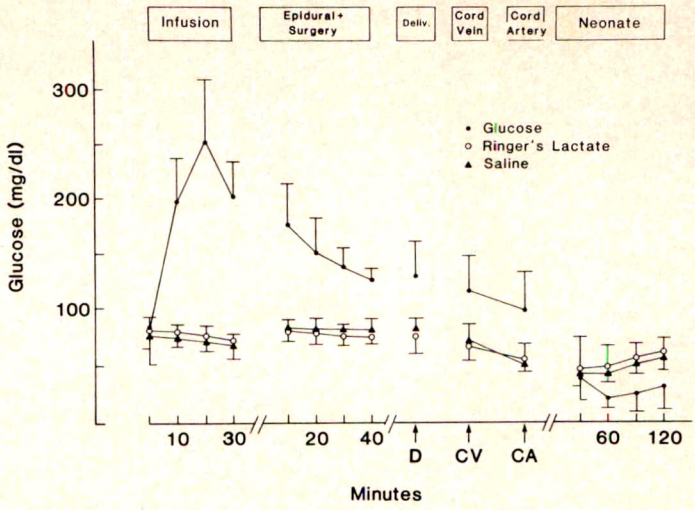

Fig. 1. Changes in plasma glucose concentration in the mother and infant after intravenous fluid administration. *D* = At delivery; *CV* = cord vein; *CA* = cord artery. Data are presented as mean ± SD.

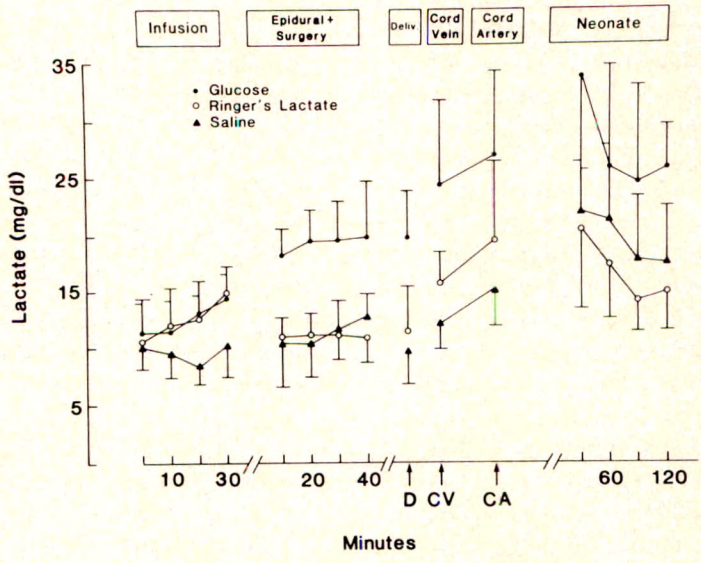

Fig. 2. Changes in blood lactate concentration in the mother and infant after intravenous administration. For abbreviations see legend to Fig. 1.

All data are presented as mean ± SD. Group comparisons were done with Student's *t* test. A p value of <0.05 was considered statistically significant.

Results

All patients were at term and did not have any underlying medical problems. As shown in Table I, there were no significant differences among the three groups in their antenatal characteristics. The neonatal birth weight and gestational age at birth were also similar between the groups. The neonates were all term sized, appropriate for gestational age, and had 5-minute Apgar scores >7. One neonate in group 1 had meconium-stained amniotic fluid below the vocal cords and had a 1-minute Apgar score of 6. The 5-minute Apgar score in this neonate was 8.

Plasma glucose. The changes in plasma glucose concentration in the three groups are displayed in Fig. 1. The initial maternal plasma glucose concentration was similar in the three groups. Acute intravenous glucose (50 gm during 30 minutes) administration in group 1 caused a rapid increase in plasma glucose concentration, reaching a maximum of 225 ± 66 mg/dl at 20 minutes followed by a continuous gradual decline. At delivery, the maternal plasma glucose level in group 1 was still significantly elevated (134 ± 37

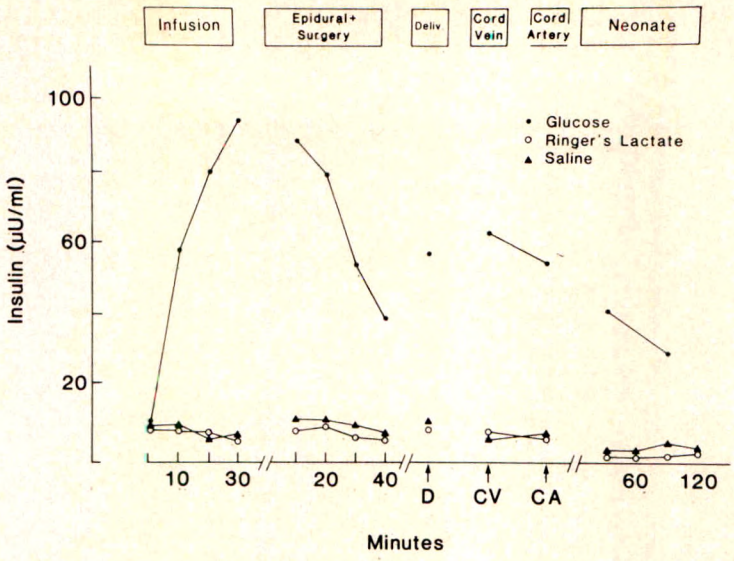

Fig. 3. Changes in plasma insulin concentration in the mother and infant after intravenous fluid administration. For abbreviations see legend to Fig. 1.

mg/dl). In contrast, acute maternal hydration with Ringer's lactate or with normal saline solution caused a small but insignificant decrease in plasma glucose concentration. The glucose concentration remained stable thereafter, so that at delivery the maternal plasma glucose concentration was 83 ± 16 mg/dl in group 2 and 76 ± 9 mg/dl in group 3.

In all three groups, the umbilical cord venous and arterial glucose concentrations were lower than the simultaneously obtained maternal peripheral venous glucose levels at delivery. However, in the group administered glucose, the umbilical cord venous and arterial glucose concentrations were significantly elevated when compared with those of groups 2 and 3 ($p < 0.001$).

Even though the glucose concentration in the umbilical cord vein and artery was higher in group 1 than in groups 2 and 3, the plasma glucose concentration in the newborn infants at 30 minutes was similar in all three groups. The plasma glucose concentration in group 1 decreased during the next 30 minutes before stabilizing during the next hour. By 2 hours after birth, the neonatal plasma glucose concentration remained significantly lower in group 1 than in groups 2 and 3 ($p < 0.01$). In contrast, the plasma glucose concentration in the newborn infants in groups 2 and 3 stabilized between 44 and 62 mg/dl for the next 90 minutes.

Four of 12 neonates in group 1 and two of 11 neonates in group 2 developed asymptomatic hypoglycemia (blood glucose value of <25 mg/dl, Dextrostix, Ames Co., Elkhart, Indiana). No infants in group 3 developed hypoglycemia. One infant in group 1 developed tachypnea. At this time, the plasma glucose concentration was 18 mg/dl.

Blood lactate. Changes in maternal, umbilical cord, and neonatal blood lactate concentrations are shown in Fig. 2. Initial maternal blood lactate concentrations in groups 1, 2, and 3 were 12 ± 3, 11 ± 3, and 10 ± 2 mg/dl, respectively. In groups 1 and 2, the maternal blood lactate concentration was significantly higher at the end of the intravenous infusion when compared with the respective initial blood lactate concentrations and also when compared with the value in the group receiving normal saline solution (group 3) ($p < 0.01$). However, by the time the epidural anesthesia was induced and surgery was begun, the blood lactate concentration in group 2 was similar to that of group 3. The maternal blood lactate concentration in the glucose infusion group remained significantly elevated throughout surgery and delivery when compared with the initial blood lactate concentration and also when compared with values in groups 2 and 3.
